Introduction and Objectives: One of requirements to be a good tennis player is to be able to quickly use visual cues from the opponent's movement to plan and execute an appropriate move. But before that, the tennis player should have a good body control to perform the movements of the upper limbs. Thus, the aim of study was to examine the effect of long-term tennis practice on the anticipatory postural adjustments (APAs) and on reaction time (RT) and movement time (MT) during a pointing to a target task.

Methods: Eight right-handed adolescent tennis players (6 males and 2 females) with at least two year of intensive practice (three or more days per week) and eight sex- and age-matched controls participated in the study. The standing participant placed each foot on a force platform (AMTI OR6-7), and pressed with the index finger of the dominant hand a force sensor (ATI Nano 17) attached to a tripod located in front of and aligned with the participant's midline. They were instructed to point one of two targets displayed on a 32-inch touch screen monitor ELO placed at a distance of 85% of the participant's arm length. The two 2.5-cm diameter circular targets were set at left and right extremities of the screen, respectively defined as contralateral and ipsilateral to the arm used to perform the movement. At the beginning of each trial both targets were displayed as dark green. The sign indicating that the pointing movement should be performed was the target changing of color (from dark to light green) changed the color. They were asked to start moving as soon as the target changed its color, to perform the movement towards the target as fast as possible, and be as accurate as possible pressing the screen at the center of the target. Ten trials were performed for each target location under a certainty condition (participant knew what target he/she should move to) or uncertain condition (movement direction was unknown until one to two targets change its color). APAs were assessed from changes in weight bearing and center of pressure (COP) displacement and movement planning and execution by RT and MT.

Results: Before starting the movement, participants presented symmetry in their weight bearing independent of the target and direction and no difference between tennis players and controls was found. Also, the COP displacement on the left limb was higher when participants had to reach the contralateral target during uncertain condition and this effect was more evident for tennis players, suggesting a greater preparation of this group for more complex condition (i.e., contralateral target on the uncertainty condition). Regarding movement planning, participants in both groups spent more time to start their movement in the uncertainty condition compared to the certainty condition (≈50 ms), but no difference between tennis players and controls was found for RT. For movement execution, results revealed no effect of direction and condition but revealed that the MT for tennis players was shorter than for controls, but only when the target reached was the contralateral one.

Conclusion: The findings indicate that long-term tennis practice did not improve individual's ability to detect the visual stimulus and plan the target-directed movement in a pointing task. However, tennis practice can cause little changes in movement execution, principally when someone has to contact a target placed contralateral to the moving limb. This increase in movement velocity could be directly related to the higher amplitude postural adjustments found in tennis players in this condition. A plausible explanation for this increased movement velocity when moving towards the contralateral target is that tennis players are more accustomed to move their upper-limb to the contralateral side of their dominant limb when they use a backhand stroke and this kind of movement is not common for individuals who do not play any racket sports.

MOTOR UNIT SYNCHRONIZATION BETWEEN QUADRICEPS MUSCLES IS TASK-DEPENDENT

Maurice Mohr [1,*] Marius Nann [2] Vinzenz von Tscharner [1] Benno Nigg [1]

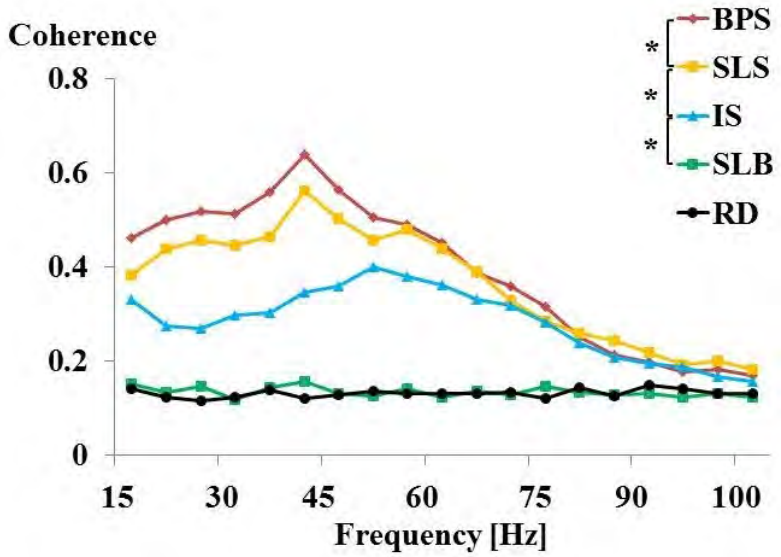
[1]Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, Canada, [2]University of Erlangen-Nuremberg, Nuremberg, Germany

Introduction and Objectives: Motor unit (MU) synchronization within and between individual muscles as a result of a common synaptic input has commonly been investigated during isometric contractions[1]. Recently, it has been suggested that MU synchronization within a muscle is task-dependent and is higher during concentric muscle contractions than during isometric contractions[2]. In consequence, MU synchronization, particularly with respect to its physiological function, should be investigated under dynamic and more natural conditions. However, for MU synchronization between two individual muscles, the presence of a task-dependence is unknown. Further, the influence of balance tasks that may require independent muscle contributions rather than synchronized muscle function is poorly understood. Therefore, the purpose of this study was to compare the synchronization of MUs between two quadriceps muscles during isometric and dynamic squats with and without balancing elements. We hypothesized (1) that concentric muscle contractions during dynamic squats demand a higher degree of MU synchronization than an isometric contraction and (2) that synchronization is reduced during balancing tasks.

Methods: Healthy, male (n=13) and female (n=5) participants (age: 25±4 years) completed an isometric squat (IS), a series of dynamic bipedal (BPS) as well as single-leg squats (SLS) and a single-leg balance task (SLB). A recently developed current amplifier[3] was used to record monopolar surface electromyograms (EMGs) from the *vastus lateralis (VL)* and *medialis (VM)*. As a measure of synchronization, coherence spectra between the raw EMGs of *VL* and *VM* were calculated between 15–100 Hz and averaged across subjects. Coherence spectra were considered significant if they were different from a random coherence spectrum (RD) that was computed between two similar but unrelated signals. Statistical differences between coherence spectra were determined using a one-way repeated measures ANOVA and Bonferroni corrected post-hoc tests (α=0.05).

Results: The coherence between *VL* and *VM* during BPS, SLS, and IS was significantly higher than the random coherence ($p<0.001$). Coherence during SLB was not significantly different from the random coherence ($p=0.416$). The highest coherence was found during BPS and decreased significantly for SLS ($p=0.008$) and IS ($p<0.001$) (Figure 1).

Figure:



Caption: Figure 1: Mean coherence spectra for bipedal squat (BPS), single-leg squat (SLS), isometric squat (IS), single-leg balance (SLB), and random coherence (RD) (n=18)

Conclusion: During BPS, IS, and SLS, MUs of *VL* and *VM* were significantly synchronized. The degree of synchronization during dynamic squats (BPS, SLS) was higher compared to an isometric squat, supporting our first hypothesis. It is assumed that the higher degree of synchronization during dynamic squats originates from an increased common synaptic input to the motor neurons of the quadriceps muscle. This might reflect a basic strategy of the central nervous system to produce force more rapidly and to simplify the execution of more complex movements[4]. The synchronization during SLS was smaller compared to BPS and there was no synchronization during a SLB, supporting our second hypothesis. We speculate that reducing the common motor input may be a central strategy to promote a more independent function of the individual quadriceps muscles in order to maintain the stability around the knee joint during a balance task[4]. The results of this study underline the importance of investigating MU synchronization during dynamic tasks rather than isometric contractions. Future research has to use similar approaches to further elaborate the functional role of synchronized quadriceps activation with respect to performance and injury outcomes.

BIOMECHANICAL COMPARISON OF ANCHORING STRENGTH OF DIFFERENT EXPANDABLE PEDICLE SCREWS IN SEVERE OSTEOPOROSIS

Ching-Lung Tai [1,*] Yi-Lu Chen [1] Cheng-Syuei Lin [1] Lih-Huei Chen [2]

[1]Graduate Institute of Medical Mechatronics, Chang Gung University, [2]Department of Orthopaedic Surgery , Chang Gung Memorial Hospital, Taoyuan, Taiwan, Republic of China

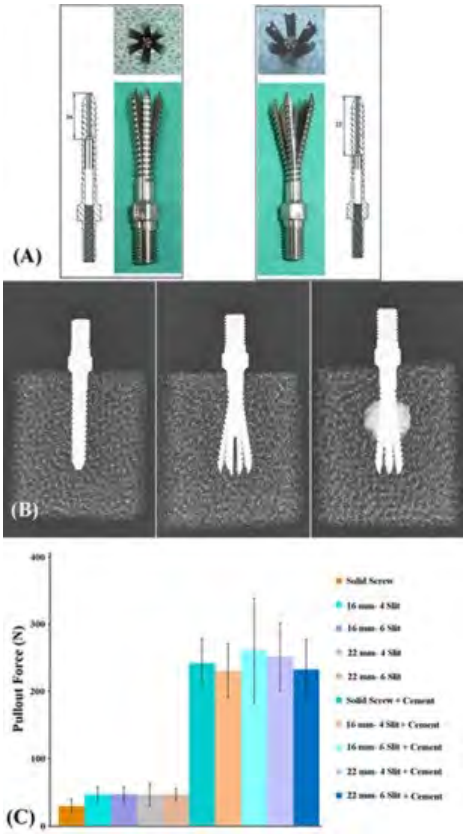
Introduction and Objectives: Pedicle screw fixation for patients with severe osteoporosis remains a challenge for the orthopedist. To solve this problem, the common surgical technique is to inject cement into vertebrae, and then secure the screw to improve the screw/bone interfacial strength. Recently, cement-injectable cannulated screws and expandable screws are used to enhance the screw holding power. To improve screw pullout strength in cannulated screw, the PMMA bone cement was squeezed to the osteoporotic bone, via the central hole of screw, and thus enhances the screw/bone interfacial strength [1]. For the expandable screws, however, the screw also has a cannulated center in which an expansion pin is placed. The anterior end of the screw is divided lengthwise to form separated wings that expand at the posterior tip after pin insertion, and hence increase the screw holding power. Expandable screws are demonstrated to significantly improve the axial pullout strength as compared to conventional screws in osteoporosis. However, previous studies addressing the influence of design parameters such as the degree of screw expansion, number of the lengthwise wings, cement augmentation or not, on the axial pullout strength of the expandable screws are lacking. This study aims to explore the effects of the above-mentioned parameters on expandable pedicle screws.

Methods: Four screw designs were employed in the present study: 4 slits and 6 slits with 16 mm or 22 mm in effective expansion length. The effective expansion length was defined as the length from the point of diameter change of the screw central hole to the screw tip. Commercially available test block (model #1522-507, Pacific Research Laboratory Inc., Vashon Island, WA, USA) was used as a substrate for vertebrae with severe osteoporosity, which eliminated the experimental errors caused by the variability of bone properties and morphometry. Prior to screw insertion, a pilot hole was drilled into the test block using a 3-mm drill bit, and a cannulated screw was then inserted into the test block through the prepared pilot hole. For screw without cement augmentation, a pin was inserted into the screw central hole to achieve screw expansion. Whereas for screw with cement augmentation, cement was injected via the central hole prior to the insertion of central pin. Pedicles screws with or without cement augmentation were then tested for axial pullout failure using an Instron testing machine (model 5544, Instron Inc., Canton, MA, USA). Screw pullout test was conducted according to ASTM F543-02 testing standards [2].

Results: The 6-slit screw with 16 and 22mm of effective expansion length after expansion was shown in Fig. 1A. The expansion diameters at the screw tip for screws with 16 and 22mm effective expansion length were 11 and 15 mm, respectively. The results revealed that the screw with a longer effective expansion length achieved a larger expansion range. The radiological examination of the screws inserted into the test blocks was shown in Fig. 1B. The radiological photograph indicated that the cement was exuded from the slits closest to the very beginning of its flow path. The mean pullout strength of various types of expandable screw was shown in Fig. 1C. Solid screw without cement augmentation

presented the lowest pullout strength (27.6±12 N). Regardless of screw designs, a significant increase of pullout strength was found for expandable screw combined with cement augmentation. Although previous literatures have shown expandable pedicle screws effectively enhance screw holding power, our results further demonstrated that expandable screw combined with cement augmentation may enormously increase screw fixation as compared to the use of expandable screw alone. The increase in both screw slit number and the degree of screw expansion has little impact in increasing screw anchoring strength.

Figure:



Caption: Fig. 1. (A) Photograph showing the pedicle screw after expansion. 6-slit screw with 16 mm of effective expansion length (left); 6-slit screw with 22mm of effective expansion length (right). Screw with 22 mm effective expansion length presents a large expansion range. (B) Radiological photograph showing pedicle screws inserted into test block. Solid screw with cement augmentation (left); Expandable screw without cement augmentation (middle); Expandable screw with cement augmentation (right). (C) The mean pullout strength of various types of expandable screw.

Conclusion: Cement augmentation is the most influential factor in improving screw pullout strength in application of expandable pedicle screws.

STABILITY ASSESSMENT OF STAND-ALONE CAGE WITH VARIOUS DESIGN PARAMETERS FOR DIRECT LATERAL INTERBODY FUSION USING FINITE ELEMENT ANALYSIS

Yong Woo Kim [1] Won Man Park [1] Dae Kyung Choi [1] Kyungsoo Kim [2] Yoon Hyuk Kim [1,*]

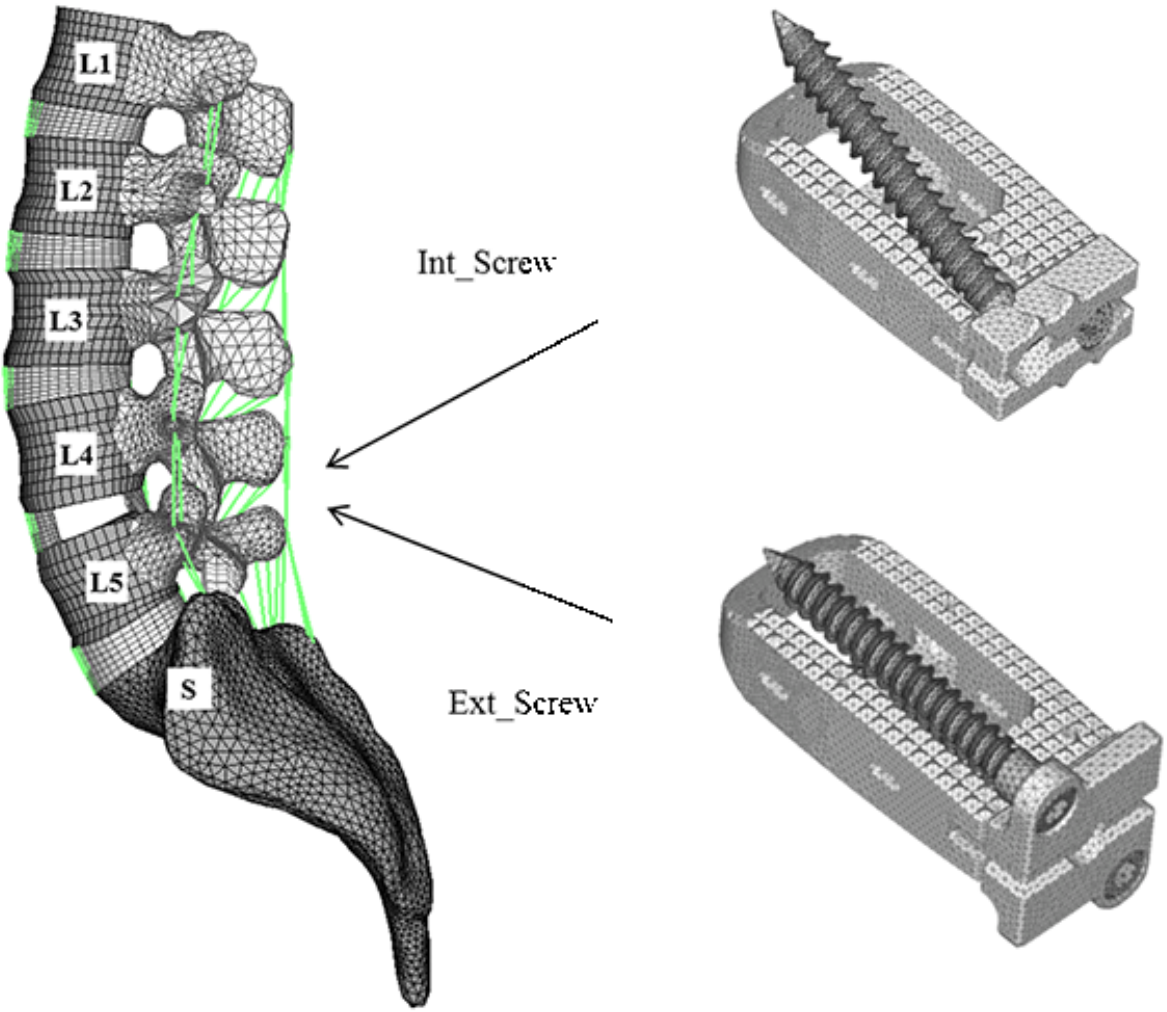
[1]Mechanical Engineering, [2]Applied Mathematics, Kyung Hee University, Yongin, Korea, Republic Of

Introduction and Objectives: Direct lateral interbody fusion (DLIF) is an effective surgical method to treat low back pain because it could be performed by a minimally invasive option. Furthermore, this method could avoid complications such as posterior bony resection, wide muscle dissection in posterior approach, and vascular injury in anterior approach. In addition, it can preserve all the ligamentous structures which were considered to be one of the major stabilizing components of the lumbar spine **[1, 2]**. However, a biomechanical study has reported that stand-alone cage system for DLIF could not provide enough stability at the operated level and suggested the utilization of supplementary fixations to improve the stability **[3]**. In order to increase stability without utilization of supplementary fixations, we investigated the effects of design parameter of stand-alone cage system for DLIF on stability at the operated level by using finite element analysis.

Methods: A validated three-dimensional finite element model of the lumbar spine from L1 to S1 was used **[4]**. Two kinds of stand-alone cages, which are a cage with two internal screws (Int_Screw) and a cage with two external screws (Ext_Screw), were used (Figure). In case of Int_Screw, the cage was completely inserted between vertebrae and screwed to upper and lower vertebrae through inferior and superior planes of vertebrae. In case of Ext_Screw, the inserted cage between vertebrae was screwed to the vertebrae with external plate on right lateral side of vertebrae. Each stand-alone cage was inserted at L4-L5 motion segment. About 68% of annulus fibrosus was removed for applying DLIF on the lumbar spine model. The initial screw angle and length were 25° and 45 mm in Int_Screw, and 5° and 45 mm in Ext_Screw. Screw angle varied from 20° to 35° and from 5° to 30° in Int_Screw and Ext_Screw cases with increments of 5°. Screw length of both types of stand-alone cages varied from 35 mm to 45 mm with increments of 5 mm. The sacrum of the healthy lumbar spine was rigidly fixed and bending moments of 10 Nm along flexion, extension, lateral bending and axial rotation were applied on the superior plane of the L1 vertebra with a compressive force of 500 N along the follower load direction. Hybrid loading conditions which generate the same overall rotation angle to the healthy lumbar spine were applied for the implanted models. The predicted ranges of motions (ROMs) at the operated level were compared with each other to evaluate the stability.

Results: The ROMs at operated level in Int_Screw decreased from 4.4°, 2.3°, 0.4°, 1.3°, 0.5°, and 0.5° to 3.8°, 2.2°, 0.4°, 1.0°, 0.5°, and 0.5° in flexion, extension, right lateral bending, left lateral bending, right axial rotation and left axial rotation, respectively, with increase in screw fixation angle from 20° to 35°, while those in Ext_Screw changed from 1.9°, 1.2°, 0.2°, 0.6°, 0.4°, and 0.5° to 1.6°, 1.0°, 0.2°, 0.5°, 0.4°, and 0.5° in case of with increase of fixation angle from 5° to 30° (Table). The ROMs in flexion and extension in Ext_Screw increased from 1.9° and 1.2° to 2.2° and 1.3°, respectively, when the length of screw was reduced from 45 mm to 35 mm. All but these two analysis cases showed slight changes in ROMs.

Figure:



Caption: Finite element models of the lumbar spine and cages with internal or external screws

Conclusion: The results of this study showed that high screw fixation angle is beneficial for stability at operated level, especially in flexion, extension and left lateral bending both in Int_Screw and Ext_Screw. The longer screws generated the higher stability only in flexion and extension in Ext_Screw. In addition, the Ext_Screw case showed quite higher stability at operated level than the Int_Screw case in all loading conditions, where this finding might be explained as the penetration of cortical bone in Ext_Screw could improve the stability. This study could present basic biomechanical information to enhance the stability in terms of screw fixation angle, screw length, and types of stand-alone cage system for DLIF, because primary stability is essential for successful surgery in the spinal fusion even if stand-alone cage system for DLIF has many advantages.

Table:

Screw fixation angles		Flexion	Extension	Right lateral bending	Left lateral bending	Right axial rotation	Left axial rotation
Int_screw	20°	4.43	2.34	0.42	1.28	0.52	0.48
	25°	4.21	2.30	0.42	1.19	0.50	0.48
	30°	3.95	2.24	0.40	0.98	0.51	0.49
	35°	3.76	2.20	0.39	0.97	0.52	0.48
Ext_screw	5°	1.91	1.19	0.17	0.58	0.37	0.53
	10°	1.89	1.16	0.17	0.57	0.37	0.54
	15°	1.79	1.09	0.17	0.56	0.37	0.53
	20°	1.71	1.06	0.17	0.55	0.37	0.53
	25°	1.66	1.00	0.16	0.54	0.37	0.53
	30°	1.56	0.96	0.16	0.54	0.37	0.53

SQUAT ASYMMETRY IN PATIENTS WITH TOTAL HIP ARTHROPLASTY: COMPARISON BETWEEN DUAL MOBILITY AND STANDARD PROSTHESES

Danilo S. Catelli [1,*] Robert Little [1] Mario Lamontagne [1] Paul E. Beaulé [2]

[1]School of Human Kinetics, [2]Division of Orthopaedic Surgery, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Dual mobility (DM) bearings have shown their capacity to increase hip range of motion (ROM) and stability while minimizing the risk of impingement [1-3]. However, it is unclear whether the improved hip ROM will lead to better functional mobility, especially during eccentric movements. Symmetry analyses in joint kinetics and kinematics have shown to be useful in highlighting potential imbalances between limbs of a patient [4] using the symmetry angle (SA), which avoids artificial inflation of results and provides a standardized scale (±100%) for interpretation [5]. The aim of this study was to compare ground reaction forces (GRF) patterns in the operated and non-operated limbs during squat descending phase, in patients having undergone either DM or a standard metal on polyethylene (MPE) bearings and healthy control participants to provide a reference for symmetry values. It was hypothesized that the DM group would get better improvement than the MPE.

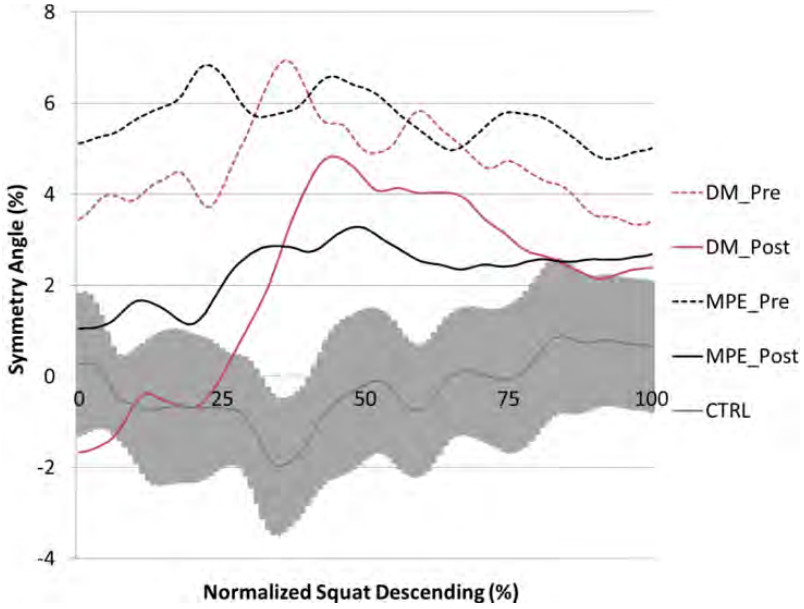
Methods: A total of 20 patients and 9 control participants (CTRL) were recruited from the orthopaedics clinic at the local hospital (Table 1). The patients who volunteered for the study were randomly assigned to either a DM or a MPE cementless total hip replacement. They also agreed to undergo to motion analysis before and nine months after THA. All surgeries were performed by the same surgeon using the direct anterior approach. The healthy participants were matched by age and BMI.

Participants performed a minimum of five squatting trials, at a self-selected pace, on two force plates (1000HZ, Bertec Corp., USA). Ground reaction force (GRF) data were processed in Nexus 1.8 (Vicon, UK) and exported to a custom MATLAB script (Mathworks, USA) to extract the variables. All trials were time-normalized during the squat descending phase, starting at maximum hip extension to maximum hip flexion angles, and individual averages for each participant were calculated across the five trials.

The method of Zifchock et al. (2008) [5] was used to calculate the SA values for all variables: $SA = (45º - \arctan(X_{operated}/X_{non\text{-}operated}))/90º * 100\%$. A SA value of 0% indicated perfect symmetry, ±100% indicated that the two values were equal and opposite in magnitude. Therefore, if $(45º - \arctan(X_{operated}/X_{non\text{-}operated})) > 90º$, the following equation was substituted by: $SA = (45º - \arctan(X_{operated}/X_{non\text{-}operated}) - 180º)/90º * 100\%$. For the CTRL group, the dominant and non-dominant legs were considered. A Wilcoxon signed-rank test, comparing pre- and post-op conditions, and a one-way ANOVA, comparing post-ops and control, were conducted for both hip kinematic parameters and SA (CI = 95%).

Results: The SA calculations show that the CTRL group remains around 0% during all task, with an average of -0.3%, while both pre-op affected groups (DM: 4.7%, MPE: 5.7%) were consistently higher than the post-ops (DM: 2.1%, MPE: 2.3%). These measures show that the operated groups still exhibited higher SA compared to the CTRL. A paired comparison between the pre and post conditions did not show a statistical difference for DM or MPE groups ($p = 0.13$ and 0.26, respectively). Also, the ANOVA among post-op and CTRL groups did not show differences ($p = 0.40$).

Figure:



Caption: Fig. 1. Symmetry angles during squat descent. The light gray shadow indicates the standard deviation around the CTRL group mean.

Conclusion: Despite the pre- and post-op paired analysis not showing a statistically SA improvement after THA, the reduction obtained in both post-THA groups could be clinically important. Interestingly, this SA reduction on post-ops was also not different from the CTRL. Post-op THA symmetry did not reach the level of the CTRL. The squat descending phase was chosen because it would represent a controlled, lower limb eccentric contraction, however, further investigations must also include concentric phase and a longer follow-up.

Table:

Group	Pre-op (n)	Post-op (n)	Age (yrs)	BMI (kg/m^2)	Sex ratio (F/M)
DM	10	10	63 ± 6	28 ± 3	4/6
MPE	9	10	61 ± 4	29 ± 5	2/8
Control	9	NA	63 ± 7	25 ± 4	2/7

THE MELBOURNE PROSTHETIC TOTAL JOINT REPLACEMENT SYSTEM FOR THE HUMAN TEMPOROMANDIBULAR JOINT

David Ackland [1,*] Adrian Moskaljuk [1] Chris Hart [2] Peter Lee [1] George Dimitroulis [3]

[1]Mechanical Engineering, University of Melbourne, Parkville, [2]Orthopaedic Surgery, [3]Maxillofacial Surgery, St Vincent's Hospital, Melbourne, Australia

Introduction and Objectives: Painful disorders involving the temporomandibular joint (TMJ), including osteoarthritis, have a prevalence ranging from 16-59% [1]. Total prosthetic TMJ replacement surgery is the established treatment for end-stage TMJ osteoarthritis; however, current TMJ prosthetic implant designs face a range of problems including fracture from metal fatigue; screw loosening; and difficulty in placement of the prosthesis to avoid screw-related damage to the mandibular nerve. The aim of this study was to develop a musculoskeletal finite element model of the TMJ based on the Visible Human Male (VHM) dataset, and to use this model to evaluate joint contact mechanics after implantation of a novel 'Melbourne' TMJ prosthetic total replacement system designed at the University of Melbourne. Unlike current prosthetic TMJ designs, the shape of the Melbourne prosthetic TMJ condyle conforms to the mandibular anatomy to make intra-operative placement more accurate, while condylar screw locations avoid the mandibular nerve.

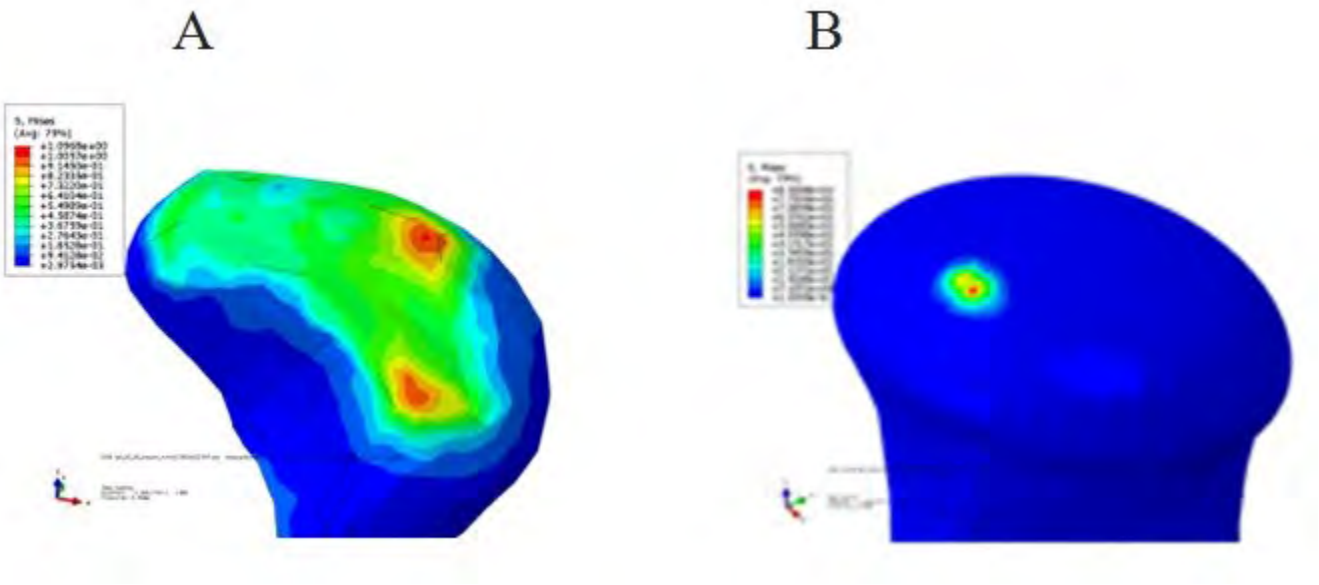
Methods: Axial images from the Visible Human Male dataset were digitally segmented and combined to reconstruct 3-D surfaces of the mandible, glenoid fossa and articular cartilage and discs. The major muscles of mastication – the masseter, temporalis (anterior and posterior), lateral and medial pterygoids – were also digitally reconstructed. Muscle lines of action, volumes and muscle fiber lengths were measured and used to calculate maximum isometric muscle force for each muscle. Using the measured muscle lines of action, and assuming ideal actuators, muscle forces during a normal chewing bite were computed by summing moments in three-dimensions about the TMJ joint centre. A static optimisation routine was used with a cost function chosen to minimise the sum of the squares of muscle activation subject to a bi-lateral bite force of 200N positioned at the second molar. TMJ contact forces were subsequently computed.

The calculated muscle forces were used as boundary conditions in a finite element model of the human jaw. The anatomy of the jaw included the three-dimensional surfaces of the mandible, glenoid fossa, articular cartilage and discs generated from the Visible Human Male dataset. A simulation of a normal chewing bite was performed and articular cartilage and disc contact stresses were calculated. The Melbourne prosthetic TMJ system was then implanted into the left TMJ of the finite element model in a virtual TMJ arthroplasty. The condylar component was fixed with three screws (superior, mid and inferior), while the fossa component was rigidly fixed to the temporal bone. Muscle and joint forces were re-calculated without the lateral pterygoid, since this muscle is severed intraoperatively. A finite element model simulation was performed to calculate implant stresses and strains during a chewing bite.

Results: The pre-operative joint reaction forces were 98.9N and 86.3N at the left and right TMJ, respectively. Pre-operatively, the maximum contact stress in the left and right condylar cartilage was 1.1MPa and 1.5MPa, respectively (Fig. 1). Post-operatively, the TMJ joint reaction force magnitudes on the left and the right TMJ were 79.1N and 78.3N, respectively. At the TMJ joint prosthesis, the maximum contact stress at the condylar component and the fossa

component was 85.0MPa and 166.1MPa, respectively. The maximum stress and strain magnitudes in the condylar component were 279.9MPa and 2253.7´10^{-6}, respectively, occurring in the region of the screw hole closest to the implant condyle head. The maximum stress of the screw at this location was 338.2MPa. Screws placed superiorly experienced higher stresses than those of all other condylar fixation screws.

Figure:



Caption: Pre-operative contact-stress distribution on condylar cartilage (A) and post-operative contact stress distribution on prosthetic condyle (B)

Conclusion: This study describes a new prosthetic TMJ, and provides estimates of muscle and joint-contact loads in the TMJ both before and after TMJ arthroplasty. While contact forces at the TMJ were of lower magnitude post-operatively, the contact stresses in the TMJ components were orders of magnitude higher than those in the pre-operative condylar cartilage. This finding indicates a potential mechanism for wear in the TMJ prosthesis. High stresses in the most superior screw-hole (closest to the condyle head) indicate risk of early screw loosening at this location if this screw is not placed carefully, or with enough fixation. This is clinically significant, since intra-operative placement of the superior screw is most difficult for the surgeon as he/she must avoid the facial nerve by working through an incision below the angle of the mandible.

PO-0166

IN VITRO WEAR TESTING OF THE MATORTHO® PIPR™ PROSTHESIS

Andrew Naylor [1,*] Ian. A Trail [2] Thomas. J Joyce [1]

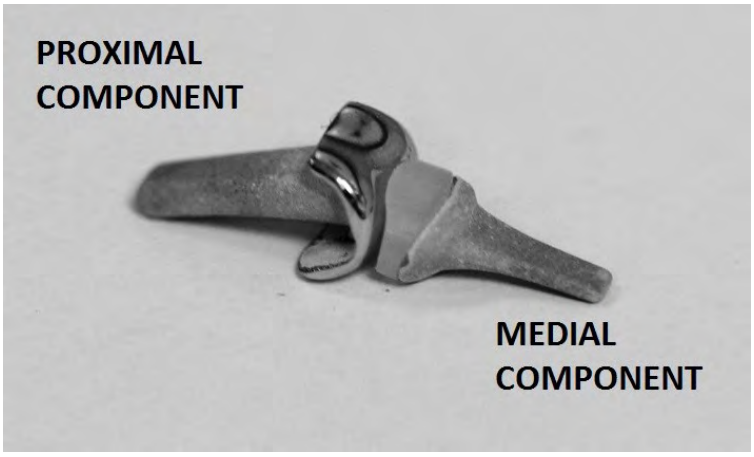
[1]School of Mechanical and Systems Engineering, Newcastle University, Newcastle upon Tyne, [2]Upper Limb Research Unit, Wrightington Hospital, Lancashire, United Kingdom

Introduction and Objectives: The MatOrtho® PIPR™ (figure 1) is an anatomical surface replacement used for arthroplasty of the proximal interphalangeal joint. The articulating surface materials are: Cobalt-chromium (CoCr) for the proximal component; and Ultra High Molecular Weight Polyethylene (UHMWPE) for the medial component, both of which are mounted on CoCr stems with a hydroxyapatite coating. The PIPR™ was first implanted in 2006 in patients who predominately have osteoarthritis. Nearly 800 have been implanted worldwide to date. The key objectives of this study were to evaluate the wear and surface roughness characteristics through testing of the PIPR™ in-vitro.

Methods: A pneumatic finger rig was used to simulate two biomechanical functions: 1) to cycle the prosthesis through flexion and extension with dynamic loads of 10-15 N; 2) to apply a static load of approx. 100N to simulate a 'pinch' (applied at 3000 cycle intervals). The simulator is described in greater detail elsewhere [1], and it has previously been used to evaluate other designs of two-piece finger prostheses [2-4]. In this study one CoCr-UHMWPE prosthesis 'test' pair was subjected to five million cycles of flexion and extension, with a 'control' prosthesis pair submerged within the test chamber to account for lubricant uptake. Wear was measured gravimetrically at one million cycle intervals using a Denver Instruments TB215D balance, measured to the nearest 0.1 mg. Roughness average (Ra) values of the articulating surfaces were obtained using a non-contacting profilometer, also at one million cycle intervals.

Results: There was a distinctive correlation between the ascending cycles of flexion-extension and gravimetric change in weight (Δm) (Table 1). The CoCr test component gradually decreased in weight over the five million test cycles, at a rate of approx. 0.7 mg per million cycles. By comparison, the weight of the CoCr control component varied only by a small amount, less than 0.1 mg per million cycles. The UHMWPE test component decreased in weight over the five million test cycles, at a rate of approx. 0.3 mg per million cycles. In contrast the UHMWPE control component increased in weight at a rate of approx. 0.1 mg per million cycles. The surface roughness results (Ra values) were inconclusive. There was no distinctive correlation between the ascending cycles of flexion-extension and Ra values. This indicates that the level of wear that occurred at articulating surfaces was negligible. Micrograph images taken at the end of testing exhibited large sections of the test prosthesis stems where little hydroxyapatite coating was present. This is in contrast to the control prosthesis stems which exhibit a more uniform coating. This loss of hydroxyapatite may explain the decrease in weight of the CoCr test component.

Figure:



Caption: Figure 1 – The MatOrtho® PIPR™

Conclusion: Both the CoCr and UHMWPE test components exhibited clear signs of gravimetric wear. Both test components decreased in weight while there was very little change for the control, in the case of CoCr, or even an increase in weight for the UHMWPE control. The inconclusive surface roughness trends provide little evidence to support that wear occurred at the articulating surfaces. The micrographs do however indicate that the hydroxyapatite coating was removed across large sections of the test prosthesis stems in-vitro. This accounts for the observed gravimetric loss.

Table:

	CoCr (Proximal) - Test	CoCr (Proximal) - Control	UHMWPE (Medial) - Test	UHMWPE (Medial) - Control
Cycles	Δm (mg)	Δm (mg)	Δm (mg)	Δm (mg)
0	0.0	0.0	0.0	0.0
1.E+06	-1.5	-0.2	-0.3	0.2
2.E+06	-2.2	-0.2	-0.5	0.4
3.E+06	-2.8	-0.3	-0.8	0.5
4.E+06	-3.2	-0.2	-1.0	0.5
5.E+06	-3.5	-0.3	-1.4	0.5

BIOMECHANICAL COMPARISON OF THE DORSAL FEMUR CONDYLES AND THE ILIAC CREST IN TERMS OF FAILURE BEHAVIOR

Rainer Penzkofer* [1], Stephan Grechenig[2], Richard Kujat[2], Peter Angele[2], Sebastian Dendorfer[1]

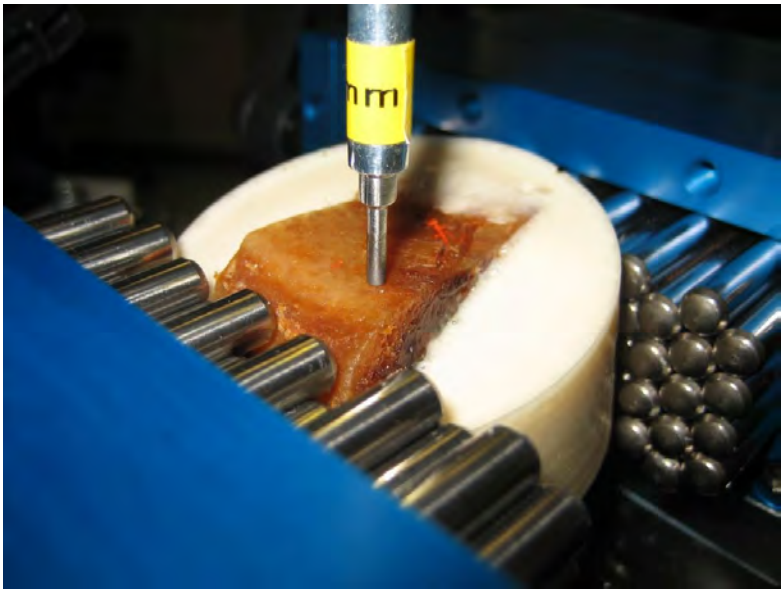
[1]Biomechanics, Regensburg Center of Biomedical Engineering, [2]University Hospital Regensburg, Regensburg, Germany

Introduction and Objectives: 10 to 12 % of the population suffer from cartilage damage in the knee joint, which in many cases leads to osteoarthritis (OA). OA is partially caused by increased forces which result from obesity. The resulting increased moments acting in the knee joint in combination with a defective position of the extremities accelerates this process even further. In addition to that, impacts resulting from accidents or overuse exercise may induce local damage altering the stress distribution on the joint surface. Beside bone marrow stimulation and autologeous chondrocytes transplantation, osteochondral transplantation is performed to replace minor subchondral defects using extracts from the iliac crest. Little is known about the treatment options for large and deep osteochondral defects. Currently it is still unclear if the mechanical properties of the iliac crest meet the biomechanical loading situation of the knee joint.
The aim of the current study was to compare the subchondral layer of the femur condyles with the cortical layer of the iliac crest concerning their biomechanical properties.

Methods: From five donors (3 male, 2 female) left and right Thiel embalmed sections of the iliac crest and the femur condyles were prepared and embedded into PU. CT scan was performed on all specimens and the Bone Mineral Density (BMD) was measured via QCT. None of the donors had signs of previous injury, abnormality or disease. The maximal strength in Newtons (N) and the failure behavior were investigated using an indenter testing procedure by loading the bone's surface with a 2mm cylindrical indenter until passing the subchondral bone zone and cortical layer, respectively. The load was applied displacement controlled at a test speed of 0.1 mm/s. A custom made clamping system guaranteed the orthogonal orientation of the area currently tested to the indenter. For each pair of specimen three kinds of tests were conducted. First (i), the iliac crest was tested. After that, the femur condyles were tested with (ii) and without (iii) the articular cartilage layer. One test again consisted of 8 subtests. From each test mean and standard deviation were calculated.

Results: The failure load of the iliac crest samples ranges from 53.3N to 180.5N. Specimen that still had an intact cartilage layer showed failure loads between 118.3N to 260.4N. Removing the cartilage layer of the femur condyles leads to a reduction of the failure load of about 20% to 80%. Concerning failure load, no significant difference could be found for samples of the iliac crest and femur condyles having their cartilage removed. Especially the condyle samples with an intact cartilage layer showed a different failure behavior in terms of an almost linear load increase until failure. Iliac crest and condyle samples without cartilage layer failed stepwise. Samples offering a low BMD showed minor load to failure values compared to those offering high BMD levels. In general specimen from male donors tend to show higher load levels than the female ones.

Figure:



Conclusion: This study showed promising results in terms of biomechanical properties of a bone block from the iliac crest compared to the subchondral layer of the femur condyles. From a mechanical view, the cortical layer of the iliac crest seems to fulfill the requirements of the subchondral bone without cartilage in the knee joint. Removing the cartilage layer leads to a decreased failure load and different failure behavior. Hence, the cartilage layer seems to be mainly responsible for the stability of the femur condyles compared to the iliac crest samples. The articular cartilage was removed from the condyle's surface by a surgeon using a scalpel. The possible damage of the bony surface may contribute to the lower failure forces compared to specimen with remaining cartilage.

Although, the histologic structure of subchondral bone of the knee joint without cartilage differs from the structure of the iliac crest material, both show comparable mechanical properties in a macroscopic local compression test performed in this study. Using autologous bone grafts for bone augmentation seems to be a good option for the regenerative therapy of large osteochondral defects.

FRONTAL PLANE KINEMATICS AND KINETICS AFTER UNICONDYLAR KNEE ARTHROPLASTY DURING ACTIVITIES OF DAILY LIVING

Igor Komnik* [1], Michaela Wehrstein[2], Sina David[1], Wolfgang Potthast[1]

[1]Institute of Biomechanics and Orthopaedics, German Sport University, Cologne, [2]Instiut für Sport und Sportwissenschaft, Karlsruher Institut für Technologie, Karlsruhe, Germany

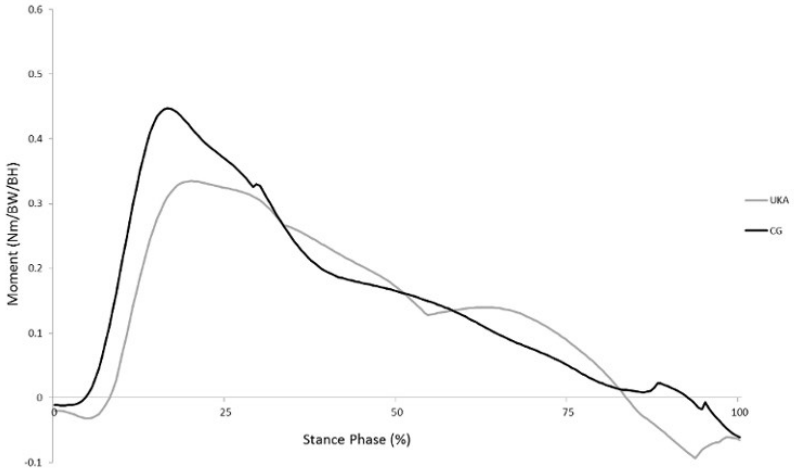
Introduction and Objectives: Currently, 4 007 400 adults older than 50 years live with a total knee Arthroplasty (TKA) in the U.S. [1]. Even though unicondylar knee arthroplasty (UKA) represents a small proportion of all knee arthroplasties, there is an increase in UKA-surgeries in the recent years [2]. Among other potential benefits of UKA compared to TKA, UKA is stated to show more normal knee kinematics and kinetics e.g. due to preservation of both cruciate ligaments [3]. Only few articles investigate UKA-patients performing activities of daily living (AODL) with optoelectronic systems. Especially high adduction moments are connected to increased polyethylene wear primarily in the medial compartment and are there of particular interest [4]. Hence, the aim of this case study is to describe frontal plane kinematics and kinetics of three UKA-patients and three healthy subjects performing four AODL.

Methods: Six male subjects participated in this case study. Three patients underwent an unilateral unicodylar knee arthroplasty (UKA-Group) at least 22 months prior to testing. The initial diagnosis was osteoarthritis with nondiseased contralateral limbs and no musculoskeletal disabilities. Three healthy subjects build the control group (CG) that was matched according to age, sex, height and BMI of the UKA-group (Table 1). Motion analysis was performed using an optoelectronic eleven-camera motion capture system (Vicon, Oxford, UK). Two force plates (Kistler, Winterthur, Switzerland) were embedded in the floor and one in the second as well as in the third step of a staircase consisting of five steps. Fifty retroreflective markers were attached to subject's feet, shank, thighs, pelvis, thorax, upper arm, lower arm and head to create a 17-segment rigid model. Kinematics and kinetics calculations were performed with AnyBody (AnyBody Technology, Aalborg, Denmark). Knee Adduction moments are presented as external moments normalized by body weight and height. The subjects completed four tasks of AODL: level walking (1.38 ±0.07 m/s), level walking + 90°-sidestep turning(1.38 ±0.07 m/s), stair ascent/descent. For each motor task five trials were averaged for data analysis. Due to the small sample size, descriptive statistics of the affected knee joint frontal plane kinematics and kinetics are presented as median (range).

Results: The following results are presented as a descriptive approach and should therefore be considered with caution. Both groups showed similar range of motion (ROM) values in the frontal plane and peak knee adduction moments during level walking. The sidestep-turning condition showed highest knee adduction moments (0.41 Nm/kg/m, range 0.28-0.57 Nm/kg/m) in the first 50% of stance phase compared to other locomotor tasks. Furthermore greater knee adduction moments occurred to the CG (0.45 Nm/kg/m, range 0.37-0.56 Nm/kg/m) than to the UKA-group (0.33 Nm/kg/m, range 0.28-0.44 Nm/kg/m) as shown in Figure 1. The UKA-group negotiated the stair ascent task with greater ROM (9.82°, range 8.99-10.23°) in the frontal plane and positioned the knee in a more abducted manner compared to the CG (CG 6.87 °, range 5.09-8.74°). In this regard the UKA-group presented in the first 50% of stance phase modest higher knee

adduction moments, but wider dispersion (UKA 2.5 Nm/kg/m, range 0.14-0.35 Nm/kg/m; CG 0.217 Nm/kg/m, range 0.216-0.218 Nm/kg/m).

Figure:



Caption: Figure 1 Median knee adduction moments course of the UKA-group and CG.

Conclusion: The results of the current case study emphasize the importance of researching besides level walking physical more demanding activities like stair negotiation and turning tasks. No kinematic and kinetic differences between the two groups were observed during level walking. Indeed, in the turning task condition the CG tended to perform this task with higher knee adduction moments, although both groups walked pre-turning with nearly the same speed of 1.38 m/s. Potential reasons for this difference could be the persistence of a pre-surgery movement pattern or unconscious avoidance of high knee loads. Further variables like e.g. angle of attack and limb-symmetry could clarify the mentioned observation and should be calculated in future studies. In general, there is a lack of knee arthroplasty articles investigating knee adduction moments during turning tasks. Only McClelland et al. [5] presented frontal plane kinetics but in patients with TKA. Future studies should involve more subjects and additionally TKA-groups.

Table:

Group	Age	BMI (kg/cm²)	Height (m)	UKA-Side	Compartment	Post-surgery (months)
KA	56	28.37	1.837	Left	Lateral	22
	56	26.45	1.83	Right	Medial	22
	57	28.72	1.77	Left	Medial	22
CG	58	27.47	1.81			
	50	26.06	1.85			
	50	25.35	1.72

DIAGNOSTIC OF ACETABULAR CUP LOOSENING WITH A NON-INVASIVE DIAGNOSTIC TECHNIQUE BASED ON VIBRATION ANALYSIS

Abdullah A. Alshuhri [1,*] Anthony W. Miles [1] James L. Cunningham [1]

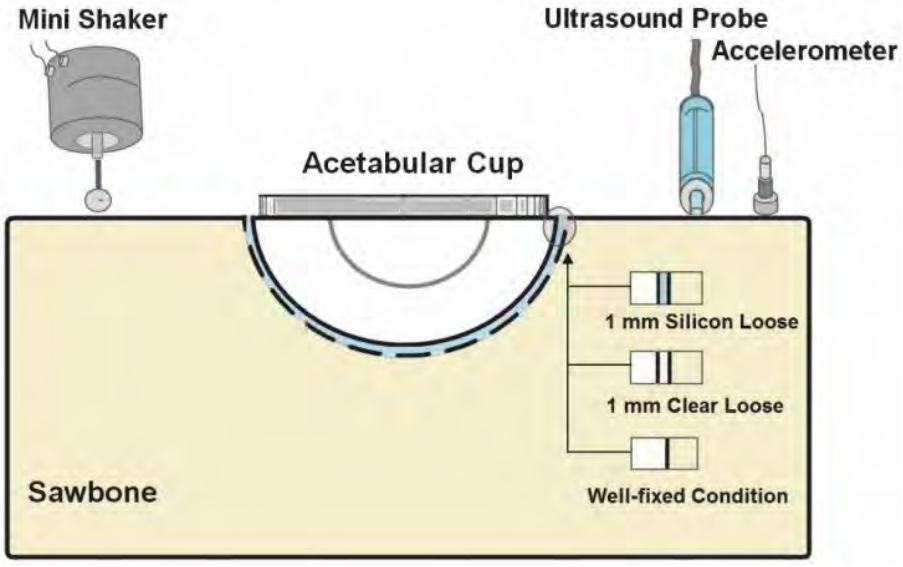
[1]The Centre for Orthopaedic Biomechanics, Department of Mechanical Engineering, University of Bath, Bath, United Kingdom

Introduction and Objectives: Well over one million total hip replacements (THR) are carried out annually around the world; a number which is only likely to increase [1]. Aseptic loosening remains a significant clinical problem, in particular associated with the acetabular cup. Current techniques for diagnosing early loosening of the acetabular cup in THR are ineffective [2]. Accordingly, the aim of this study was to investigate the viability of using vibrational analysis for accurately detecting early acetabular component loosening.

Methods: A simplified acetabular model was constructed using a Sawbone® foam block into which an acetabular cup was fitted. Loosening of 1 mm was simulated by the interposition of thin layer of silicon between the acetabular component and the Sawbone block. A constant amplitude sinusoidal excitation with a sweep range of 100–1500 Hz was used. Output vibration from the model was measured using an accelerometer and an ultrasound probe. Loosening was determined from output signal features such as the number and relative strength of the observed harmonic frequencies.

Results: Both measurement methods were sufficient to measure the output vibration; however the ultrasound measurements were of a clearly higher magnitude than accelerometer readings throughout the frequency range. Different patterns in the output signal spectra were visible when comparing the stable cup with the 1mm of simulated loosening at the higher frequency range.

Figure:



Caption: The Sawbone block showing the excitation and measurement methods.

Conclusion: These preliminary findings show that vibration analysis could potentially be a reliable method for detecting acetabular component loosening using either an accelerometer or ultrasound probe. However, the capacity of ultrasound to overcome the attenuating effect of the surrounding soft tissues and its high signal to noise ratio suggest it has the best potential for clinical use.

THE EVALUATION OF BONE REMODELING AROUND TWO TYPES OF ACETABULAR CUPS

Tongtong Guo [1],*Yan Wang [1]

[1]Nature Science Department, Harbin Institute of Technology Shenzhen Graduate School, SHENZHEN, China

Introduction and Objectives:

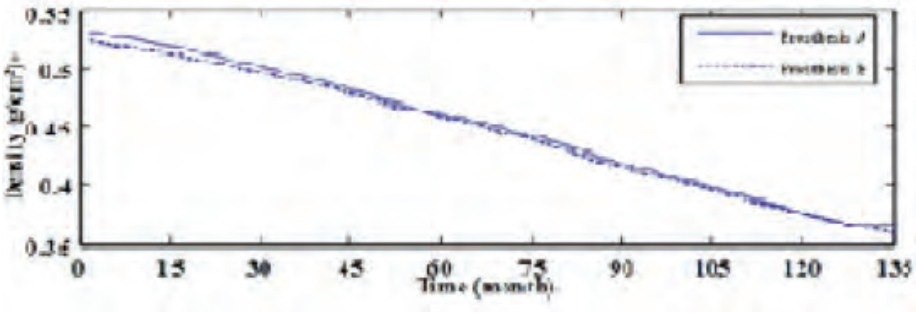
The design of acetabular cups is essential for THA operation results. The main purpose of this study is to compare long-term bone remodeling results around two kinds of acetabular cups after THA operation.

Methods:

Hip geometry model applied in this study is from CT scan [Ho Ba Tho, 2003]. The elements of cortical bone and acetabular cup in this model are defined as solid elements, the ones of cancellous bone are shell elements. Hip is divided into 18662 elements. Ischium and ilium are fixed constraints. One type acetabular cup is from the patent (Type A)[Ho Ba Tho, 2004], the other is the general type (Type B). The contact between hip and acetabular cup is defined as a rigid - elastic contact body, and friction coefficient is 0.25. Bone remodeling algorithm is applied to predict long term THA results in two types of hip - acetabular models.

Results: The long-term bone density of two hips with prosthesis implantation is obtained at 135 months after THA operation. From the distribution graphs of total density and cancellous bone density, we can see that the number of elements being absorbed of prosthesis B is more than that of prosthesis A; after 135 months implantation of prosthesis, acetabular bone with prosthesis B is absorbed 1310 units, whereas the one with prosthesis A is absorbed 1203 units. The hip with prothesis A is about to reach a bone remodeling equilibrium after 130 months, however, acetabular bone mineral density with prothesis B is still in declining (Figure 1).

Figure:



Caption: Figure 1

Conclusion:

The stress concentration of prosthesis B is more serious than prosthesis A, and the initial maximum and average strain energy density energy density of prosthesis B is larger than prosthesis A.

The number of being absorped elements of prosthesis B is more than prosthesis A, and the absorption speed of prosthesis B is faster. From the total density variation figuer, when bone remodeling with prosthesis type A reaches equilibrium, the one with prosthesis type B is still in the process of bone resorption.

MUSCLE MECHANICS OF UPPER LIMB INVOLVED IN THE DESIGNING OF PROSTHETIC HAND WITH MOVING FINGERS

Nitin Sahai [1,*] Sudip Paul [1] Dinesh Bhatia [1] Angana Saikia [1]

[1]DEPARTMENT OF BIOMEDICAL ENGINEERING, NORTH EASTERN HILL UNIVERSITY, SHILLONG, MEGHALAYA, INDIA, SHILLONG, India

Introduction and Objectives: Rehabilitation has long lacked a unifying conceptual framework. Rehabilitation is a set of measures that assist an individual who experience, or are likely to experience, disability to achieve and maintain optimal functioning in interaction with their environments. An “ideal” upper limb prosthesis should be perceived as part of the natural body by the amputee and should replicate sensory-motor capabilities of the amputated limb. However, such an ideal “cybernetic” prosthesis is still far from reality. Current prosthetic hands are simple grippers with one or two degrees of freedom (DOF), which barely restore the capability of the thumb index pinch. Upper-limb amputations are most often the result of sudden trauma to the body, although they also can be caused by malignancy, congenital deficiencies, and vascular disease. This paper describes muscles involvement during movement of fingers, thumb and the development of a cost-effective and acceptable prosthetic hand which can restore the lost function and bear resemblance to natural hand having a long life span with maximum load bearing capacity. There are 35 muscles involved in movement of the forearm and hand, with many of these involved in gripping activities. Bio-signals based natural gesture recognition is one of the most active thrust area of rehabilitation robotics.

Our objectives are:-

1. To find out whether signals from these muscles are helpful in development of prosthetic hand with moving fingers

This study is a part of research grant sponsored by government to develop low cost artificial prosthetic hand with moving fingers for amputees.

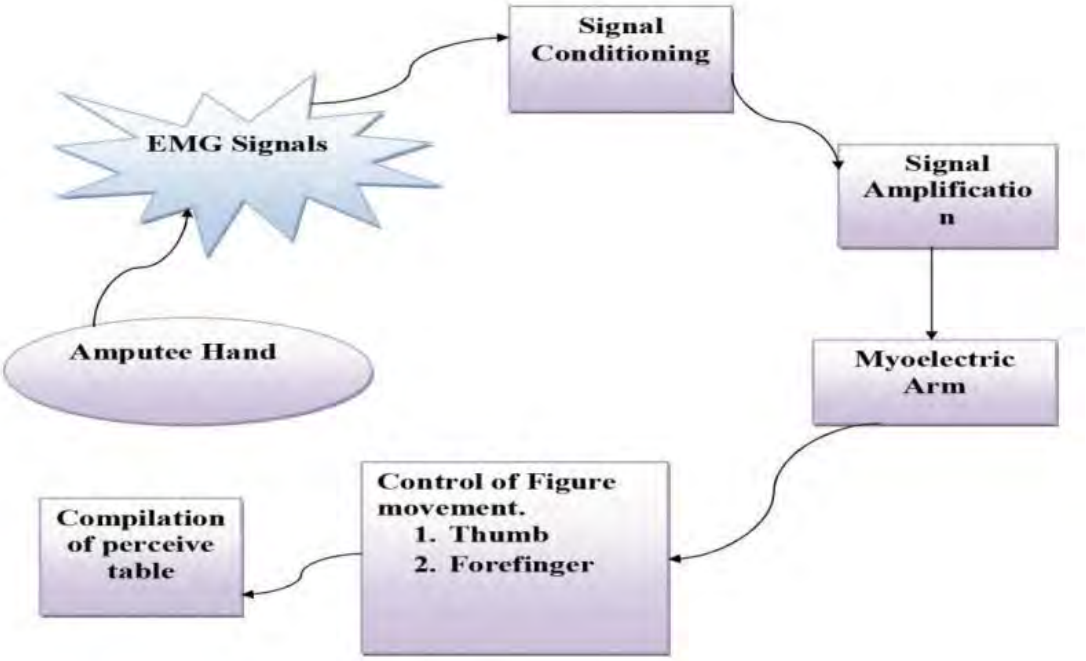
Methods: In the present work, individuals of different sex and age group were employed for studying the muscle activity of upper limb. The EMG signal was recorded from the selected muscles of human hand of these subjects by placing surface electrodes (Ag-Agcl), as they performed fingers and palm motion like flexion and extension, abduction and adduction of hand. Here we have used AD Instruments Power Lab 4/ 25T for signal acquisition. Signal conditioning of muscle signals obtained was performed post signal amplification to determine the actual activity of individual muscles involved during the motion of fingers and thumb. These signals would help in developing the proposed myoelectric arm.

Results: The observations were made after concluding from the data obtained, that the following muscles showed higher percentage movements of index finger, namely as, Extensor Digitorum muscle for Extension of finger, Flexor Digitorum Superficialis muscle for the flexion of finger, Dorsal Interossei muscle for the adduction of finger and Plamar Interossei muscle for the abduction of finger. In second phase of this paper, we will correlate how these findings would help us in designing of prosthetic hand with moving fingers.

The following are the recognition rates of the four types of muscles for the movement of the index finger (Figure 1)

The experimental results shows that the movement of the index finger using the four different muscles mentioned above showed the highest recognition rate. Further, it has been found that the overall detection accuracy rates obtained are in the acceptable range of the clinical tests. These results could be employed for the design of the prosthetic hand with moving fingers. The classified signal can be efficiently used to develop a human computer interface to help the people with disabilities who wish to interact with computer devices and outside world.

Figure:



Caption: Study protocol with experimental model

Conclusion: The presented research article will conclude that economical cost effective myoelectric arm can be developed which can restore overall functions of a normal human hand, thus improving the quality of life of individual.

Table:

MOVEMENTS	MUSCLES	RECOGNITION RATE
Flexion	Flexor Digitorum Superficialis muscle	75%
Extension	Extensor Digitorum Muscle	80%
Adduction	Dorsal Interossei Muscle	85%
Abduction	Plamar Interossei Muscle	90%

PO-0172

COMPARISON ON NONLINEAR REGRESSION ALGORITHMS FOR PREDICTION OF SKIN TEMPERATURE IN LOWER LIMB PROSTHESES

Neha Mathur [1,*] Ivan Glesk [1] Arjan Buis [2]

[1]Electronic and Electrical Engineering, [2]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

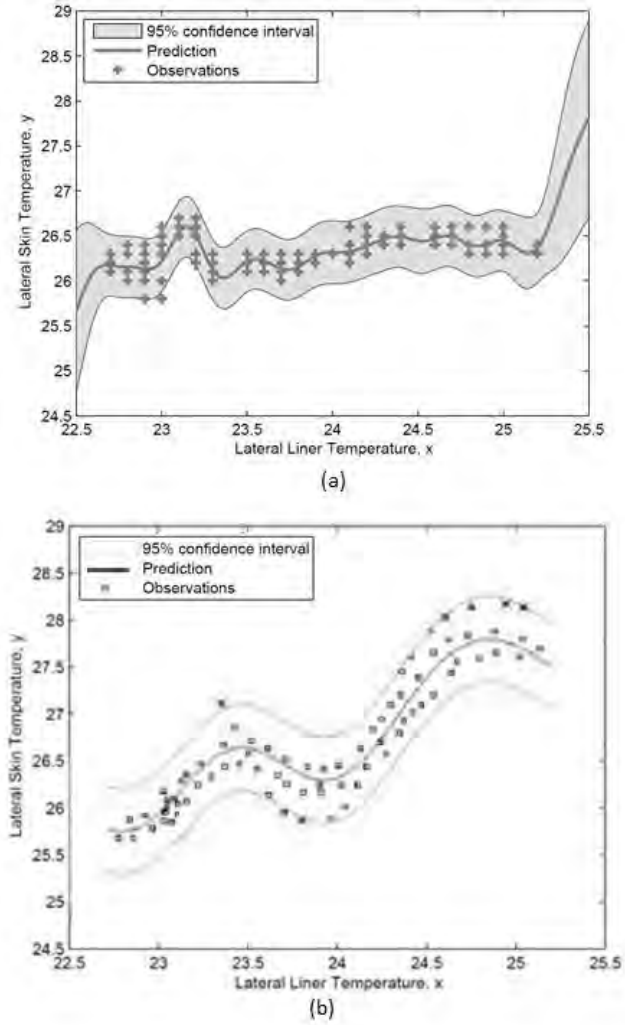
Introduction and Objectives: Monitoring and predicting the residual limb skin health in amputees is of principal importance as the socket of the prosthesis creates an airtight, warm and damp environment that encourages growth of bacteria and skin breakdown.Elevated stump skin temperatures are one of the major factors that affect the tissue health in that region [1].Monitoring interface temperature at skin level is notoriously complicated as embedding wires and sensors in an elastomer eventually results in elastomer failures because of the high strain induced when donning a liner. Another reason is because placing sensors and wires directly against the skin could cause irritation and chaffing over just a short period of time.The heat dissipation in prosthetic sockets is greatly influenced by the thermal conductive properties of the socket and interface liner materials [2].This leads to a hypothesis that if the thermal properties of the socket & liner materials are known then the in-socket stump temperature could be accurately predicted by just measuring the prosthetic socket or liner temperature.A mathematical model using the Gaussian processes for machine learning to predict the residual limb skin temperature of the amputee by measuring the in-socket temperature has been developed [3].Here we compare the performance of Gaussian processes for regression (GPR) to the other computational method namely support vector machines (SVM).

Methods: To investigate the correlation between the position of thermocouples (skin and in-socket), one trans-tibial traumatic amputee was recruited to perform in a 35 minute laboratory protocol (see Table). To monitor and record the skin and in-socket temperatures, four K–type thermocouples via a data logger were used.Two thermocouples were taped onto the residual limb in lateral and medial position.The other two thermocouples were put on the corresponding positions on the liner (in-socket).The temperature profiles of the liner and the residual limb skin were recorded for ambient temperatures of 10°C, and then the same protocol was repeated for 15°C, 20°C, and 25°C. All experiments were conducted in a climate controlled chamber with zero wind velocity and 40% humidity level.It was seen that at any given ambient temperature, the trace of the liner temperature follows that of the residual limb skin.This suggested a possibility to model the liner temperature as a function of skin temperature and create a mathematical model of the same.Different modelling techniques for machine learning were utilized and the results from the Gaussian processes model and support vector regression technique are compared in this study.

Results: The results (Figure) indicate the predictive capability of both Gaussian Processes and SVM modelling techniques at the lateral side at an ambient temperature of 10ºC.The key assumption in Gaussian Process modelling is that our data can be represented as a sample from a multivariate Gaussian distribution. A Gaussian process model infers a joint probability distribution over all possible outputs for all inputs.This form enables the implementation of Bayesian framework where the covariance function is taken in the squared exponential form which specifies the set of hyperparameters.After optimizing the hyperparameters, the predictions lie in the 95% confidence interval (±2 standard deviations).This is

indicated in (a) in the figure.The SVM modelling technique relies on defining the loss function that ignores errors, which are situated within the certain distance of true value.This epsilon intensive loss function measures the cost of the errors on the training points. In order to optimize it, the least squares cost function is used.This enables the predictions from the model to lie in 95% confidence interval (see (b) in figure).

Figure:



Caption: Illustration of prediction of residual limb skin temperature at 10°C with (a) Gaussian Processes (b) Support Vector Machine

Conclusion: The results presented in this work show the feasibility of non-invasively monitoring the residual limb skin temperature by utilizing two mathematical regression algorithms.The accuracy of predictions of residual limb temperature estimated by SVM with least squares kernel and GPR with squared exponential covariance function is 95%.For all the experimental data sets, estimation with GPR yielded values that closely matched the true values, whereas SVM showed comparable performance only for temperatures of 10ºC and 15ºC.These results indicate that GPR with a squared

exponential covariance function is better suited than SVM to reliably determine residual limb temperature from liner temperature experimental data.Furthermore the GPR based determination requires less computational time.

RELATIONSHIP OF LOWER-LIMB MUSCLE STRENGTH AND STANDING ABILITY TO WALKING SPEED AND GAIT CYCLE VARIABILITY IN COMMUNITY-DWELLING OLDER PEOPLE

Wakako Inoue [1 2,*] Tome Ikezoe [1 2] Ikuya Sato [1 2] Katarzyna Malinowska [1 2] Takahisa Kawaguchi [2 3] Yasuharu Tabara [2 3] Takeo Nakayama [2 4] Fumihiko Matsuda [2 3] Tadao Tsuboyama [1 2] Noriaki Ichihashi [1 2]

[1]Human Health Sciences, Kyoto University Graduate School of Medicine, [2]The Nagahama Study group, Kyoto University, [3]Center for Genomic Medicine, Kyoto University Graduate School of Medicine, [4]Department of Health Informatics, Kyoto University Graduate School of Public Health, Kyoto, Japan

Introduction and Objectives: Decreased walking speed and increased gait cycle variability have been associated with the risk of falling in older adults. Therefore, therapeutic exercises aimed at improving walking speed and reducing gait cycle variability may help to prevent falls in this population. However, few studies have focused on the relationships between walking speed, gait cycle variability, and muscle strength including the strength of the hips, knees, and toes. The purpose of this study was to determine the relationship of gait speed and gait cycle variability to lower-limb muscle strength and standing ability in community-dwelling older adults.

Methods: The subjects comprised 205 community-dwelling, healthy, older adults (69 men, 136 women, aged 67.5±5.0 years). Subjects with physical dysfunctions that could potentially have influenced measurements, such as acute neurological impairment, severe musculoskeletal impairment, or severe cognitive impairment, were excluded.

Lower-limb muscle strength was determined by measuring the maximal isometric strength of hip flexion, extension, and abduction, knee extension (at 90-degree flexed position), quadriceps muscle setting, and toe grip strength. Strength during quadriceps muscle setting was measured with a specialized device (Locomoscan, Alcare Co., Ltd. Tokyo, Japan) that utilized a force sensor placed in the popliteal region while the subject sat with their knees fixed at 20° flexion and their hips and ankles held in place with belts. One-legged standing time with the eyes open was considered to represent standing ability.

Walking speed and gait cycle variability were evaluated at a comfortable walking pace and while walking as quickly as possible. Walking speed was measured over 12 m, with the subjects allowed 2 m to accelerate before measurements began. Gait cycle variability was assessed using a wireless sensor consisting of a triaxial accelerometer, magnetic sensor, and triaxial gyroscope (G-walk, Bertec Japan Co., Ltd. Kanagawa, Japan) to detect the heel contact during each step. The coefficient of variation (CV) was calculated from the mean value and standard deviation (SD) of the duration of eight steps (from the fourth through the eleventh step; CV = 100 × SD / mean value). This CV was used as the index of gait cycle variability.

Stepwise regression analysis was performed with walking speed and CV as dependent variables and lower-limb muscle strength and one-legged standing time as independent variables. P values of < 0.05 were considered statistically significant.

Results: Walking speed was 1.5 ± 0.2 m/s at a comfortable pace and 2.0 ± 0.3 m/s at maximum speed. The CVs were 3.4 ± 1.7% and 4.6 ± 2.8% at a comfortable and maximum pace, respectively.

At a comfortable walking speed, stepwise regression analysis showed that only quadriceps muscle setting strength (standardized coefficient = 0.23) was a significant and independent determinant of speed (R^2 = 0.06). Only one-legged standing time (standardized coefficient = −0.21) was a significant and independent determinant of CV (gait cycle variability) during comfortable walking (R^2 = 0.04).
At maximum walking speed, stepwise regression analysis revealed that one-legged standing time (standardized coefficient = 0.26), knee extension strength (standardized coefficient = 0.22), and quadriceps muscle setting strength (standardized coefficient = 0.16) were significant and independent determinants of speed (R^2 = 0.21). No variables were identified as significant determinants of CV during walking at maximum pace.
Conclusion: This study showed that quadriceps muscle setting strength was a significant and independent determinant of both comfortable walking speed and maximum walking speed. Thus, strength of quadriceps setting among lower-limb muscle strength may be associated with walking speed in community-dwelling older adults. In addition, our results suggest that gait cycle variability during comfortable walking may be more closely related to one-legged standing ability than to lower-limb muscle strength.

SONOGRAPHIC ASSESSMENT OF SUPRASPINATUS TENDINOPATHY AS A FUTURE DIAGNOSTIC AND EFFECT MEASURE – A RELIABILITY STUDY OF THE ASSESSMENT METHOD

Kim G. Ingwersen [1 2,*] John Hjarbaek [3] Henrik Eshoej [1] Camilla Marie Larsen [1] Jette Vobbe [4] Birgit Juul-Kristensen [1 5]

[1]Institute of Sports Science and Clinical Biomechanics, Faculty of Health Sciences, University of Southern Denmark, Odense M, [2]Department of physiotherapy, Hospital Lillebaelt, Vejle Hospital, Vejle, [3]Department of radiology, Musculoskeletal section, Odense University Hospital, Odense, [4]Orthopaedic Department, Shoulder Unit, Hospital Lillebaelt, Vejle Hospital, Vejle, Denmark, [5]Institute of Occupational Therapy, Physiotherapy and Radiography, Department of Health Sciences, Bergen University College, Bergen, Norway

Introduction and Objectives: Rotator cuff tendinopathy is a common condition in the shoulder, most often involving the supraspinatus tendon. The causes are numerous and pathogenesis unclear, but during recent years it has been proposed that tendinopathy should be regarded as a continuum of stages, where structural changes in the tendon can range from a normal to a pathologic tendon [1]. The stage of tendinopathy has great influence on the rehabilitation that is considered appropriate. Anamnesis and combinations of special clinical orthopaedic tests are often used when diagnosing rotator cuff tendinopathy, but these tests are often lacking good specificity and sensitivity. Sonographic visualization of structural changes in the rotator cuff is therefore often used to confirm rotator cuff tendinopathy, and can possibly aid in deciding the specific stage of tendinopathy.

Sonography is an operator dependent technique, and is highly influenced by the performers expectations, experience and technique. Therefore, a standardized procedure is necessary in order to obtain reliable assessments.

Thus, we sought to develop a standardised sonographic method to assess and classify pathological changes in the supraspinatus tendon, which may be associated with supraspinatus tendinopathy, and test inter-examiner reliability of this assessment method.

Methods: A standardized procedure for obtaining sonographic pictures and movie sequences of the supraspinatus tendon was developed, ensuring that relevant changes regarding tendon thickness, hypoecchoic areas, fibrillar disruption, calcification and neovascularity were visualized optimally. A modified version of a grading scale, proposed by Poltawski et al. 2012 [2], was developed for grading the potential pathological characteristics. The modified scale consists of a 0-1 score for assessing the presence of fibrillar disruption, calcification and neovascularity. A grey-scale picture was obtained at a fixed point for evaluating tendon thickness.

Five healthy participants and five participants with shoulder discomfort were used in the development and training phase. Afterwards, in the inter-tester reliability study a sample of 10 participants with no shoulder discomfort and 10 participants diagnosed with supraspinatus tendinopathy were included. The primary investigator (rater A) performed all sonography scans. Demographic information regarding age, gender, arm dominance and Self-reported shoulder function scored on “Disability of the Arm, Shoulder and Hand questionnaire’’ (DASH), was obtained at the same time as the sonography scan. In order to secure blinding of rater A, all data were stored for at least four weeks, before they were analyzed. Two

raters (A and B) independently viewed the obtained picture and movie sequences, measured tendon thickness and assessed the presence of calcification, fibrillar disruption, and neovascularity.
Cohen's Kappa statistics were used for the dichotomized scale of fibrillar disruption, neovascularization and calcification. ICC statistics were used for measurement of tendon thickness. MDC for tendon thickness was calculated based on the ICC-value. The difference in height between rater A and B was tested with a paired t-test in order to evaluate potential systematic differences between rater A and B.
All statistics were performed in Stata/IC 13.1 (StataCorp, Texas, USA).
Results: There was no statistically significant difference in age, gender, height or hand dominance between participants with and without shoulder discomfort. A significant difference was, as expected, found on the patient reported outcome score "Disability of the Arm, Shoulder and Hand questionnaire'' (DASH) between participants with and without shoulder discomfort. Kappa-values were substantial for calcification (0.76), perfect for neovascularization (1.0), but poor for fibrillar disruption (0.08). The ICC was 0.73 for tendon thickness and MDC was 1.7mm. A non-significant (p=0.23) difference of 0.25mm (SD 0.9) in measured tendon thickness was found between rater A and B.
Conclusion: The standardized method for assessing supraspinatus tendinopathy showed good inter-examiner reliability in measuring thickness, calcification and neovascularization, and the MDC indicates that even small changes in tendon thickness are detectable. The standardized protocol for assessing fibrillar disruption needs to be reevaluated and retested before further research with this assessment methode can be performed.
In order to increase the likelihood of clinicians choosing the most appropriate rehabilitation strategy, based on the specific stage of tendinopathy, the assessment method must be reliable and sensitive. This trial takes a step towards using a standardized method for sonographic scanning of the supraspinatus tendon and a standardized assessment of the observed changes that relate to the stages of tendinopathy.

EFFECTS OF DIFFERENT METATARSAL PAD DESIGNS AND PLACEMENTS ON PLANTAR PRESSURE DISTRIBUTION

Weng-Pin Chen [1,*] Shih-Cherng Lin [2] Sih-Chen Huang [1] Fuk-Tan Tang [2]

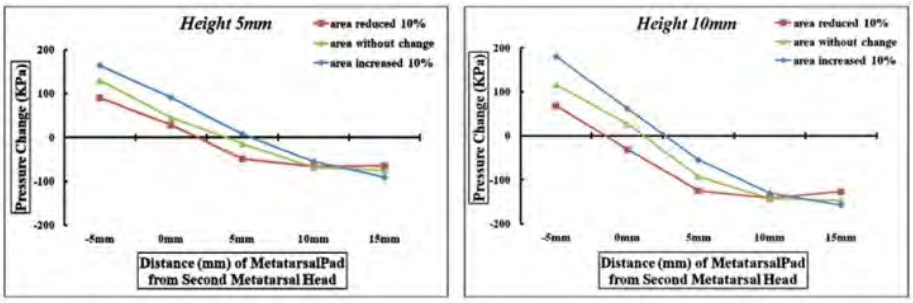
[1]Mechanical Engineering, National Taipei University of Technology, Taipei, [2]Physical Medicine and Rehabilitation, Chang-Gung Memorial Hospital, Taoyuan, Taiwan, Republic of China

Introduction and Objectives: Due to the load transfer mechanism, the propulsive ground reaction force is often concentrated on the area beneath the first and second metatarsal heads during human ambulation. The pain and discomfort resulted at this area are known as metatarsalgia. In order to relieve this symptom, metatarsal pad is commonly prescribed for patients with metatarsalgia in clinical practice. Although the effectiveness of metatarsal pad on the plantar pressure reduction had been investigated in previous studies using plantar pressure measurement system, the experiment itself is very difficult to eliminate the relative motion between the foot sole and insole, and to define the location precisely. For this reason, no clear conclusion on the metatarsal pad design and placement that can achieve best effectiveness in plantar pressure reduction so far. Due to the finite element analysis has the advantages in modifying the model and adjusting the parameters easily, this study aimed to investigate the effects of different placements and geometrical designs of metatarsal pad on the plantar pressure distribution through dynamic finite element analysis.

Methods: A three-dimensional finite element model of the foot-shoe complex, including the foot bony and ligamentous structure, soft tissue, metatarsal pad, insole, outsole and shoe cover, was adopted in this study. The trajectory of the reflective markers and the kinematic data of the foot obtained from gait analysis were used to define the boundary condition in the finite element analysis. After validation of the model, the effects of metatarsal pad on the plantar pressure distribution beneath the metatarsus and the second metatarsal head were investigated by changing five different placements, two different heights, and three different sizes of the metatarsal pad.

Results: According to the results from the dynamic finite element analysis, when the pad was placed 10 mm proximal to the second metatarsal head, better efficacy of pressure reduction than other placements was found. Under the appropriate placement, the efficacy would be further improved by raising the height of the pad from 5 mm to 10 mm, but causing high pressure concentration beneath the metatarsus. However, increasing the pad size by 10% would relieve the concentrated high pressure.

Figure:



Caption: The changes in peak pressure under five different placements, three different bottom areas and two different heights, compared with the condition without using MT pad beneath the region of second MT head.

Conclusion: As a result, increasing the height as well as area of metatarsal pad properly may enhance the efficacy of plantar pressure reduction beneath the second metatarsal head, and relieve high pressure concentration beneath the metatarsus. The current results from the dynamic finite element analysis were focused on one single subject. Different foot dimension and structural classification were not considered in this study. More subjects with different size and structure of foot should be recruited in the future in order to provide a more comprehensive recommendation on the prescription of metatarsal pad.

PO-0176

ASSESSMENT OF SCAPULAR POSITIONING AND FUNCTION AS FUTURE EFFECT MEASURE OF SHOULDER INTERVENTIONS – AN INTER-EXAMINER RELIABILITY STUDY

Henrik Eshoj [1,*] Camilla Marie Larsen [1] Kim Gordon Ingwersen [1] Karen Sogaard [1] Birgit Juul-Kristensen [1 2]

[1]Institute of Sports Science and Clinical Biomechanics, Faculty of Health Sciences, University of Southern Denmark, Odense M, Denmark, [2]Department of Health Sciences, Institute of Occupational Therapy, Physiotherapy and Radiography, Bergen University College, Bergen, Norway

Introduction and Objectives: Scapular dyskinesis, defined as an abnormal positioning, and/or altered function of the scapular is often present in subacromial impingement syndrome (SIS). SIS is one of the most common shoulder disorders, potentially leading to degenerative conditions and/or osteoarthritis in the glenohumeral joint. Treatment of SIS primarily consists of physical therapy aiming at reducing signs of scapular dyskinesis. However, no consensus exists regarding which clinical tests to use for identifying and measuring scapular positioning and function. As a first step acceptable clinimetric measures of reliability is important, although, several tests have only been tested for intra-examiner reliability. The objective was to investigate the inter-examiner reliability of an extended battery of clinical tests for assessing scapular positioning and function.

Methods: A standardized three-phase protocol for clinical reliability studies was conducted, containing a training, an overall agreement and a study phase. The index condition (scapular dyskinesis) was defined as a clearly obvious scapular winging (pseudo or margo medialis winging) observed during bilateral repeated active flexion's of the upper extremity. A total of 24 clinical assessment variables were compiled into three categories; static (6), semi-dynamic (7) and dynamic assessment variables (9), besides assessment of external rotational strength (2). Testers were blinded to the status of subjects, the results of each test round and each others´ test results. Intra-class correlation coefficients (ICC) and kappa values were interpreted as: 0.0-0.40 (poor); 0.40-0.75 (fair to good); and 0.75-1.00 (good to excellent).

Results: A total of 41 subjects (23 males, yrs 25±9), were recruited among adult overhead athletes from the municipality of Odense, DK. Prevalence of the index condition was 54 %. Data was tested and found to have normal distribution for all continuous variables and Bland Altman plots showed no funnel effects. Bland Altman plots found no systematic bias and good to excellent ICC values in four of the static assessment variables. The ICC values ranged from "fair to good" (n=2 assessment variables, av) and "good to excellent" (n=6 av) in the static and external shoulder rotation strength (n=2 av); from "poor" (n=3 av) to "fair to good" (n=4 av) in the semi-dynamic av, with; from "poor" (n=4 av) to "fair to good" (n=3 av) in the dynamic av, and no kappa statistics computed in three tests due to constant measurements from one of the testers.

Conclusion: An extended assessment battery to investigate the inter-examiner reliability for assessing the scapular positioning and function were compiled. Systematic bias between testers appeared in some, but not all assessment methods, questioning the overall accuracy. However, within the static assessment methods, four of these had ICC values within "good to excellent" and no systematic bias. Improvements of clinimetric properties of assessment methods for measuring scapular dyskinesis are needed.

PO-0177

THE ADDITION OF MANUAL THERAPY TO AN EXERCISE PROTOCOL DOES NOT AUGMENT THE EFFECTS ON PAIN, FUNCTION AND SCAPULAR KINEMATICS IN INDIVIDUALS WITH SHOULDER IMPINGEMENT – RANDOMIZED CONTROLLED TRIAL

Paula Camargo [1,*] Francisco Alburquerque-Sendín [2] Mariana Avila [3] Melina Haik [3] Amilton Vieira [3] Tania Salvini [3]

[1]Physical Therapy, UFSCar, [2]University of Salamanca, [3]UFSCar, São Carlos, Brazil

Introduction and Objectives: Many conservative treatments have been proposed to manage shoulder impingement (SI). Systematic reviews have indicated that stretching and strengthening exercises are effective to improve pain and disability in individuals with SI, however there is still conflicting evidence for the effectiveness of manual therapy as an add-on therapy to exercises. More studies are necessary to determine if adding manual therapy techniques into a standardized exercise program is better than exercises alone. The aim of this study was to evaluate the effects of stretching and strengthening exercises associated or not with manual therapy on pain, function and scapular kinematics in individuals with SI.

Methods: Forty-six patients participated in this study and were randomly assigned to one of the 2 groups: exercise only group (14 males and 9 females, 32.65 ± 10.73 years, 68.35 ± 10.79kg, 1.69 ± 0.02m) and manual therapy + exercises group (10 males and 13 females, 35.96 ± 12.08 years, 67.04 ± 13.12Kg, 1.69 ± 0.12m). Pain during movement and greatest pain at last week were measured by a visual analogue scale. All participants also completed the DASH questionnaire to assess function of the upper limbs and scapular kinematics was assessed during elevation of the arm in the sagittal plane. The outcomes were measured 3 times over a period of 5 – 6 weeks. Individuals were first evaluated and then, started the intervention period up to 1 week after the first evaluation. Second and third evaluations were carried out after 2 and 4 weeks of intervention, respectively. Both groups were treated with stretching exercises targeting the upper trapezius, pectoralis minor and posterior shoulder, and strengthening exercises targeting the external rotators of the arm, lower trapezius and serratus anterior muscle. These exercises were selected based on alterations already identified in the SI condition. The manual therapy + exercises group also received techniques of manual therapy focused on the shoulder complex, shoulder girdle, cervical spine and upper thoracic spine. A 2-factor ANOVA (group x evaluation) was conducted for the pain and DASH, and a 3-factor ANOVA (group x angle x evaluation) for each scapular rotation. Alfa level was set at .05.

Results: Pain during movement, the greatest pain at last week and the DASH score decrease ($P<0.05$) along time independent of the intervention applied. Few improvements in scapular motion were also observed along time in both groups ($P<0.05$). Scapular internal rotation decreased (<3.7°) at 120° of arm elevation and upward rotation increased (<2.5°) at 90° and 120° of arm elevation. No significant changes were found for scapular tilt ($P>0.05$).

Conclusion: The findings indicate that the addition of manual therapy to an exercise protocol is not superior than exercises only to improve pain, function and scapular kinematics in individuals with SI. Both groups improved independent of the intervention received. Improvements in pain and function are not likely explained by changes in scapular motion once these alterations in scapular motion are not clinically relevant.

TREADMILL TRAINING AND TRANSCRANIAL DIRECT CURRENT STIMULATION OVER THE CEREBELLAR REGION IN SIX CHILDREN WITH ATAXIC CEREBRAL PALSY

Luanda Greco [1 2] Natália Duarte [1] Manuela Galli [3] Felipe Fregni [2] Claudia Oliveira [1,*]

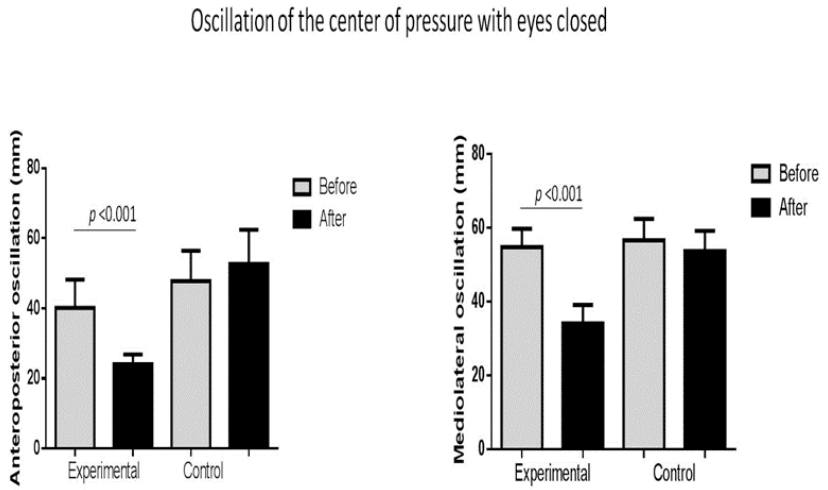
[1]Rehabilitation Sciences, UNINOVE, São Paulo, Brazil, [2]Department of Physical Medicine & Rehabilitation, Harvard Medical School, Boston, United States, [3]Department of Electronics, Information and Bioengineering, DEIB, Politecnico di Milano, Milan, Italy

Introduction and Objectives: Previous studies have demonstrated that anodal transcranial direct current stimulation (tDCS) over primary motor cortex can regulate corticospinal excitability.(1) Stimulation applied to the motor cortex during motor training is associated with improved performance and motor learning.(2-5) In children with cerebral palsy, the combination the motor training and anodal tDCS has demonstrated beneficial effects on gait and motor function.(4, 5) The aim the present study was to analyze the effects of anodal tDCS over the cerebellar region combined with treadmill training for improving balance in children with ataxic cerebral palsy.

Methods: Six children with ataxic cerebral palsy received two interventions separated by four months. The order of the interventions (experimental or control) was determined by simple randomization. The experimental intervention involved anodal tDCS and the control intervention involved sham stimulation over the cerebellar region (Oz) during treadmill training. The patients underwent the same intensive gait training program. Five weekly 30-minute sessions were performed over two consecutive weeks. Evaluations of static (oscillations of the center of pressure in the anteroposterior and mediolateral directions with eyes open and eyes closed) and functional balance (Pediatric Balance Scale) were performed before and after the interventions as well as at follow up.

Results: The experimental intervention achieved better results regarding anteroposterior oscillation with eyes open (experimental intervention: 26.2±3.7 to 20.4±4.19 mm; control intervention: 25.7±4.1 to 20.9±2.9 mm), anteroposterior oscillation with eyes closed (experimental intervention: 40.1±8.0 to 24.0±2.8 mm; control intervention: 47.7±8.6 to 52.6±9.7 mm), mediolateral oscillation with eyes open (experimental intervention: 54.7±4.9 to 34.1±4.9 mm; control intervention: 56.6±5.8 to 53.7±5.4 mm), mediolateral oscillation with eyes closed (experimental intervention: 42.9±6.7 to 30.7±2.9 mm; control intervention: 40.4±7.3 to 38.6±8.1 mm) and functional balance (experimental intervention: 38.2±2.1 to 44.2±2.3; control intervention: 40.1±3.5 to 43.2±4.1). A significant decrease in all oscillations with eyes closed was achieved with the experimental intervention in comparison to the control intervention (Figure 1).

Figure:



Caption: Results of the oscillation of the center pressure with eyes closed before and after control and experimental intervention.

Conclusion: The present findings support the hypothesis that anodal tDCS over the cerebellar region (Oz) combined with treadmill training could be a useful tool for improving static balance in children with ataxic cerebral palsy.

PO-0179

EFFECTS OF TRANSCRANIAL DIRECT CURRENT STIMULATION COMBINED WITH FUNCTIONAL UPPER LIMB TRAINING IN A CHILD WITH HEMIPARETIC CEREBRAL PALSY: A CASE REPORT

Renata Moura [1,*] Cibele Santos [1] Roberta Lazzari [1] Arislander Dumont [1] Veronica Cimolin [2] Claudia oliveira [1]

[1]Rehabilitation Sciences, UNINOVE, São Paulo, Brazil, [2]Department of Electronics, Information and Bioengineering, DEIB, Politecnico di Milano, Milan, Italy

Introduction and Objectives: Cerebral palsy (CP) is the most prevalent form of physical disability in children. Nearly 50% of children with CP have impaired upper limb function. Children with hemiparetic CP seldom use their paretic hand spontaneously in daily activities. Thus, increasing attention in the last decade has focused on upper limb rehabilitation in this population.[1] Transcranial direct current stimulation (tDCS) can be used during motor therapy sessions and involves the administration of a weak electrical current and induces lasting changes in cortex excitability in both animals and humans. In rehabilitation programs, the aim of tDCS is to enhance local synaptic efficiency, thereby altering the maladaptive plasticity pattern that emerges following a brain lesion. Stimulation is used to modulate cortex activity by opening a pathway to increase and prolong functional gains achieved in physical therapy.[2]

The aims of the present study were to determine the effects of tDCS applied over the primary motor cortex combined with functional upper limb training in a child with hemiparetic cerebral palsy.

Methods: This study received approval from the Human Research Ethics Committee of the UNINOVE (Brazil) under process number 525935/2014. The 12-year-old child had a diagnosis of left hemiparetic spastic CP, Manual Ability Classification System II, no history of surgery or neurolytic block in the previous 12 months, absence of orthopedic deformities, absence of epilepsy and no metal implants in the skull or hearing aids. The kinematic evaluation of the upper limb was performed using the SMART-D 140® system and using SMARTAnalyser software (BTS, Italy). The child was asked to reach an object on a desk in front of the patient at a normalised distance (80% of subject's arm length); the subject is seated with flexed arm flexed on the desk. The task was repeated 12 times (six movements, right and left). Kinematic analysis was conducted identifying and computing specific parameters of movement duration, velocity, smoothness and upper limbs angles[3,4]. The patient was assessed before and after training. A control Group (CG) of ten healthy children was included[4]. The child underwent the 10-session intervention protocol involving functional upper limb training combined with tDCS stimulation. The anodal electrode was positioned over the primary motor cortex of the hemisphere with the lesion following the 10–20 International Electroencephalogram System[5] and the cathode was positioned in the supra-orbital region on the contralateral side. A 1-mA current was applied over the primary motor cortex for 20 minutes as the child performed upper limb training, which involved motor strategy reach and move objects while maintaining the elbow extended.

Results: Table 1 displays the variables analyzed for the paretic upper limb (left side) at baseline (trial 1) and after training (Trial 2) in terms of kinematics. From these data, it is possible to observe a reduction of going and returning phase duration, an improvement of NJS and NMU parameters after training; mean velocity and its peak increased in the Trial 2, too

Conclusion: Studies involving use of tDCS in the rehabilitation of patients with cerebral palsy suggest that this method is safe and clinically relevant[2]. The findings of the present study demonstrate that the combination of functional upper limb training and tDCS is capable of potentiating improvements in children with CP.

Table: Table 1: Values of the analyzed parameters for the paretic upper limb.

Time parameters	Trial 1	Trial 2	Control Group
Going Phase (s)	0.9± 0.02	0.648± 0.06	0.6±0.1
Adjusting phase (s)	0.126+ 0.037	0.11+ 0.24	0.28+ 0.15
Returning Phase(s)	0.9 ± 0.021	0.616± 0.025	0.7±0.2
Smoothness			
IC(mean)(Index of Curvature)	1.04	1.046	1.1 ±0.1
NJS (Normalised Jerk Score)	222.43	97.452	226.89±124.78
NMU (Number of Unit Movement)	5.2	2.2	2.4±1.56
Velocity			
Mean Velocity (m/s)	0.582± 0.015	0.768± 0.07	0.64±0.16
Peak Velocity (m/s)	1.004± 0.053	1.258± 0.102	2.2±0.2
Accuracy			
End Point Error (mm)	9.1± 0.8	18.8± 2.1	14.2±7.5
Adjusting Sway (mm)	12	20.8	9.87±7.32

PO-0180

A BIOMECHANICAL EVALUATION OF THE COMBINED ELEVATION TEST

Sam Allen [1,*] Steve McCaig [2] Gemma Phillips [1]

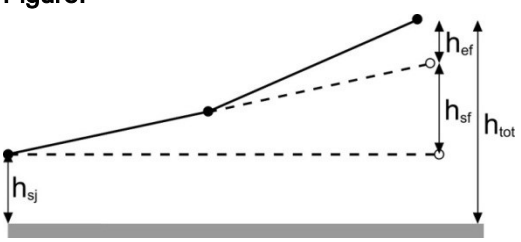
[1]Loughborough University, [2]England and Wales Cricket Board, Loughborough, United Kingdom

Introduction and Objectives: The Combined Elevation Test is a widely recognised musculoskeletal (MSK) screening tool, used across a variety of sports including, but not limited to, cricket, rugby union, swimming and triathlon [1]. The Combined Elevation Test is thought to identify impairments in strength and range of motion during synchronised thoracic extension, glenohumeral joint (GHJ) flexion, and retraction and upward rotation of the scapula [2]; however its efficacy has not yet been quantified. The outcome of the Combined Elevation Test is recorded in one of two ways. One technique adopted by [1] uses the angle created between the raised humerus and the horizontal; a more widely adopted technique is measurement to the nearest 0.1 cm, of the perpendicular height between the resting surface and the base of the first metacarpal [2]. The objectives of this study were to evaluate the Combined Elevation Test biomechanically in terms of the relationship between the outcome and its component joint motions and thoracic spine angles between test positions, genders, and different methods of measurement.

Methods: Eighteen subjects participated in the study: eleven males (age: 24.5 ± 3.1 yrs, height: 1.82 ± 0.05 m, weight: 75.3 ± 7.4 kg); and seven females (age: 23.6 ± 4.1 yrs, height: 1.73 ± 0.04 m, weight: 62.8 ± 6.8 kg). Subjects were all either elite swimmers or elite triathletes. Performance in the Combined Elevation Test was measured in two head positions: forehead in contact with the ground; and chin in contact with the ground. Individual contributions to the test outcome of: shoulder joint retraction (used as a proxy for scapular retraction and rotation); glenohumeral joint flexion; and elbow joint flexion were calculated using automatic motion capture (Figure 1). Upper, lower, and total thoracic spine angles were also calculated. Both perpendicular height of the wrist, and humeral angle were measured. Relationships between individual test components and outcome, and the effects of gender, head position, and measurement method were investigated statistically.

Results: There were no differences in any variables between males and females in any of the test components, or between head positions. Subjects scored more highly on the test in the forehead position than the chin position (34.3 cm vs 30.2 cm; $p<0.001$). The variables most strongly associated with test performance in both head positions were glenohumeral joint flexion ($r = 0.86 – 0.97$), shoulder retraction ($r = 0.75 – 0.82$), and total thoracic spine angle ($r = -0.40 – -0.44$). The use of humeral angle as a test measure was strongly, but not perfectly, related to wrist height ($r = 0.93$; $p<0.001$).

Figure:



Caption: Figure 1. The contributions of each joint to test performance: hsj is the height of the shoulder joint centre; hsf is the contribution of shoulder flexion, assuming no elbow flexion; hef is the contribution of elbow flexion; and htot is the total vertical displacement of the WJC. (n.b. hsf and hef values can be negative).

Conclusion: Within the group in this study none of the combined elevation test outcomes were different in any way between genders, therefore males and females within this subject group can be assessed using the same norms. Performance in the test was greater in the forehead than chin position due to increased shoulder retraction. The results of the correlations between test components and outcomes indicated that the component with the strongest relationship to test outcome was glenohumeral joint flexion, the second strongest predictor of test outcome was shoulder joint retraction, whilst elbow joint flexion was not related to test outcome. Total thoracic spine angle was related to test outcome but this relationship was not statistically significant. These results lend weight to the claim that the test measures GHJ flexion, and retraction and upward rotation of the scapula, and that it may also relate to thoracic extension. Humeral angle represents a good predictor of test performance but does not incorporate some aspects of the test, such as shoulder retraction, so perpendicular height of the wrist is a more suitable measure if this information is required.

Table:

	forehead		chin	
measure	male (n=11)	female (n=7)	male (n=11)	female (n=7)
h_{tot} (cm)	34.0 ± 10.0	34.8 ± 11.7	30.5 ± 10.9	29.8 ± 12.2
h_{sj} (cm)	21.3 ± 2.0	20.0 ± 2.3	19.8 ± 2.5	18.5 ± 3.0
h_{sf} (cm)	7.8 ± 9.9	9.6 ± 9.8	6.6 ± 10.5	7.0 ± 10.3
h_{ef} (cm)	4.9 ± 3.0	5.2 ± 1.5	4.1 ± 5.9	4.3 ± 3.0
T_1-T_{12} (°)	12.2 ± 5.3	13.3 ± 3.7	12.6 ± 4.9	12.8 ± 4.4
T_1-T_8 (°)	10.2 ± 4.9	8.9 ± 5.4	9.9 ± 4.7	8.6 ± 4.2
T_4-T_{12} (°)	10.5 ± 3.6	11.7 ± 2.5	11.1 ± 3.3	12.0 ± 3.2

PO-0181

FUNCTIONAL EVALUATION OF PEDIATRIC CANCER PATIENTS AFTER A 4-WEEK CLINICAL REHAB PROGRAM

Dieter Rosenbaum [1,*] Carsten Müller [1] Konstantin Krauth [2]

[1]Movement Analysis Lab, Inst. Exp. Musculoskeletal Medicine, University Hospital Münster, Münster, [2]Klinik Bad Oexen, Bad Oeynhausen, Germany

Introduction and Objectives: Children that are affected by oncologic diseases experience a life-threatening situation and have to undergo a long intensive treatment that might involve chemotherapy, radiation, resection surgery with subsequent limitations in functional capacity and quality of life. In order to help them to recover a stationary rehabilitation is part of the treatment plan in Germany. Such a rehab program aims to improve potential functional deficits and strengthen physical, psychological, and social resources.

The present project set out to evaluate the functional status, level of activity and quality of life of pediatric cancer patients before and after a 4-week rehab program with a maximum follow-up of 12 months. More specifically, we wanted to evaluate the long-term effects of the rehab program, and to determine which patient groups would benefit more or less.

Methods: Pediatric patients between 4 and 18 years of age who had been treated for brain (n=63), bone and soft tissue tumors (n=38) as well as leukemia and lymphoma (n=109) were contacted before admission to 4-week stay in the rehab clinic Bad Oexen. If time allowed for it, they were asked to wear a step counter for a week before admission to the clinic. In the clinic, patients were asked to complete a questionnaire regarding quality of life and to wear a step counter (SAM Stepwatch Activity Monitor, Orthocare Innovations, USA). Furthermore, patients with a potentially impaired gait function were also evaluated with 2-dimensional gait analysis (2 video cameras and analysis with TEMPLO 6.0, Contemplas, Germany) and foot loading measurements (emed-m/R, Novel GmbH, Germany) in the beginning and at the end of the rehab program.The measurements were analyzed with respect to the symmetry of gait or foot loading by determining a symmetry index for temporal-spatial, kinematic and kinetic parameters.

Results: The gait analysis revealed no major changes in the overall gait parameters but indicated a decrease of the degree of asymmetry during the rehab program with respect to the step length, single-leg stance and swing duration, and maximum knee flexion angle.

The foot loading parameters remained stable but the slightly increased maximum forces indicated a more dynamic gait pattern. Again, the asymmetry indices were reduced.

The balance tests showed a significantly improved function with a longer single-leg stance duration (8.6à9.6 s; p=.001) and less sway velocity (6.8à6.4 cm/s; p=.010). Analysis of the different diagnostic groups indicated that bone tumor patients are likely to have more pronounced functional deficits than brain tumor patients.

Conclusion: In general, the results demonstrated the effectiveness of the 4-week stationary rehab program and allowed for an objective evaluation of the individual progress or deficit. Patients improved the overall gait symmetry and especially bone tumor patients with an affected lower extremity benefitted from the therapy. The functional assessments might help to personalize the treatment regimens to the patient's individual needs.

STRENGHT AND HEALTH RELATED QUALITY OF LIFE IMPROVEMENT OF INDIVIDUALS WITH SHOULDER IMPINGEMENT SUBMITTED TO MOTOR CONTROL AND STRENGTHENING EXERCISES – PARTIAL RESULTS

Gisele H. Hotta [1] Adriane Santos [1] Anamaria Oliveira [1,*]

[1] Biomechanics, Medicine and Rehabilitation of Locomotor System, University of São Paulo, Ribeirão Preto School of Medicine, RIbeirão Preto, São Paulo, Brazil

Introduction and Objectives: The adequate scapular motion is important to shoulder's function. Subjects with shoulder impingement have decrease upward rotation and posterior tilt, and increase in medial rotation of scapula relative to the thorax [1]. These alterations are associated with less recruitment of scapulothoracic muscles [1,2] and less health related quality of life [3]. Objective this study is to evaluate the isometric force and quality of life the subjects submitted to protocol of motor control and muscle strengthening for scapulothoracic muscles.

Methods: Inclusion criteria were painful arc and Neer or Hawkins-Kennedy positive test, dyskinesis type I or II and a history of shoulder pain lasting more than a week in the anterolateral proximal region of shoulder. The study was approved by the Ethics Committee of the Clinic's Hospital of the Ribeirão Preto School of Medicine of the University of São Paulo. The subjects were submitted to the motor control exercises protocol for scapula and strengthening muscle, specific to serratus anterior, middle and lower trapezius and rhomboids strengthening (Figure 1). Exercises were performed three times a week for eight weeks and each session consisted of three sets of ten repetitions with initial load of 60% of 1 repetition maximum recommended by American College of Medicine Sports [4]. The protocol is specific for serratus anterior, middle trapezius, lower trapezius and rhomboids strengthening.

The evaluations were carried out before and after eight weeks of motor control and strengthening program. Assessment the strength muscles performed with load cell. Subjects were positioning according Kendall et al. (2007) and performed three repetition maximum voluntary contractions. For assessment health related quality of life was used the Shoulder Pain and Disability Index – SPADI Brazil. The SPADI contains 13 items that assess two domains; a 5-item subscale that measures pain and an 8-item subscale that measures disability. A mean is taken of the two subscales to give a total score out of 100 and higher score indicating greater impairment or disability [6]. Only data from painful shoulder were used for analysis. The Student's t-test was used to compare mean values isometric force and SPADI-Brazil total score, pre- and post-eight weeks of treatment. Level of significance was set at 5%.

Results: Twenty five volunteers were submitted to protocol. They presented mean age of 47.3 (±9.4) years old. Fourteen subjects were male. After protocol, subjects presented lesser score in the SPADI, indicating less impairment and disability and consequently improvement quality of life. The SPADI scores improved above ten points. These changes were statistically significant ($p<0.00$; Table 1) and met the minimally clinically important difference (MCID) [3]. Worsley and colleagues (2012) performed a training of motor control for scapula during ten weeks in subjects with shoulder impingement and also found clinically important quality of life improvement after treatment.

Streghthening muscle was observed for middle trapezius and serratus anterior ($p<0.05$; Table 1). The trapezius and serratus anterior have been recognized as muscles wich can stabilize and rotate the scapula and they are the prime

movers for scapular upward rotation [8]. The middle trapezius is ideally suited for scapular external rotation and serratus presents substantial mechanical advantage for upward rotation, posteriorly tilt and externally rotate the scapula [9].

Figure:

Caption: Figure 1: Motor control exercises (A-B) and muscle strengthening (C-D)

Conclusion: According to the partial results of this non-controlled study, the motor control and strengthening program could change the strength muscle and improvement health related quality of life, however, effect sizes in the complete sample should be calculated to estimate the power of the final findings.

Table:

Table 1: Comparison of pre and post treatment of Shoulder Pain And Disability Index – SPADI Brazil (total score) and muscle isometric force (Kgf) variables.

	Pre treatment	Post treatment	p value
SPADI - Brazil	48.10 ± 17.94	12.61 ± 14.39	0.000
Middle Trapezius	7.07 ± 4.85	14.10 ± 17.97	0.045
Lower Trapezius	8.00 ± 6.48	14.85 ± 17.81	0.077
Serratus Anterior	11.28 ± 5.48	19.27 ± 15.97	0.024
Rhomboids	6.68 ± 4.81	13.58 ± 17.74	0.055
Values expressed as mean ± standard deviation. Kgf: Kilogram-force

COMPENSATORY MECHANICS DURING STAIR ASCENT IN PATIENTS WITH MEDIAL KNEE OSTEOARTHRITIS; AN ANALYSIS OF MECHANICAL ENERGY TRANSFER IN THE LOWER EXTREMITY.

Yumiko Koyama [1,*] Hiroshige Tateuchi [1] Xiang Ji [1] Riho Nhishimura [1] Hiroki Umegaki [1] Masashi Kobayashi [2] Noriaki Ichihashi [1]

[1]Human Health Sciences, Graduate School of Medicine, Kyoto University, [2]Kobayashi Orthopedic Clinic, Kyoto, Japan

Introduction and Objectives: Patients with knee osteoarthritis (knee OA) often complain about their difficulties in stair negotiation, which would limit their mobility independence and increase the risk of falls. Stair ascent requires much energy generated in the lower extremities compared to level walking. Although these patients are supposed to climb stairs with certain compensatory mechanics, there is no study that disclose such compensatory strategies regarding mechanical energy efficiency. The purpose of this study was to evaluate mechanical energy efficiency during stair ascent in order to clarify the compensatory strategies in patients with knee OA.

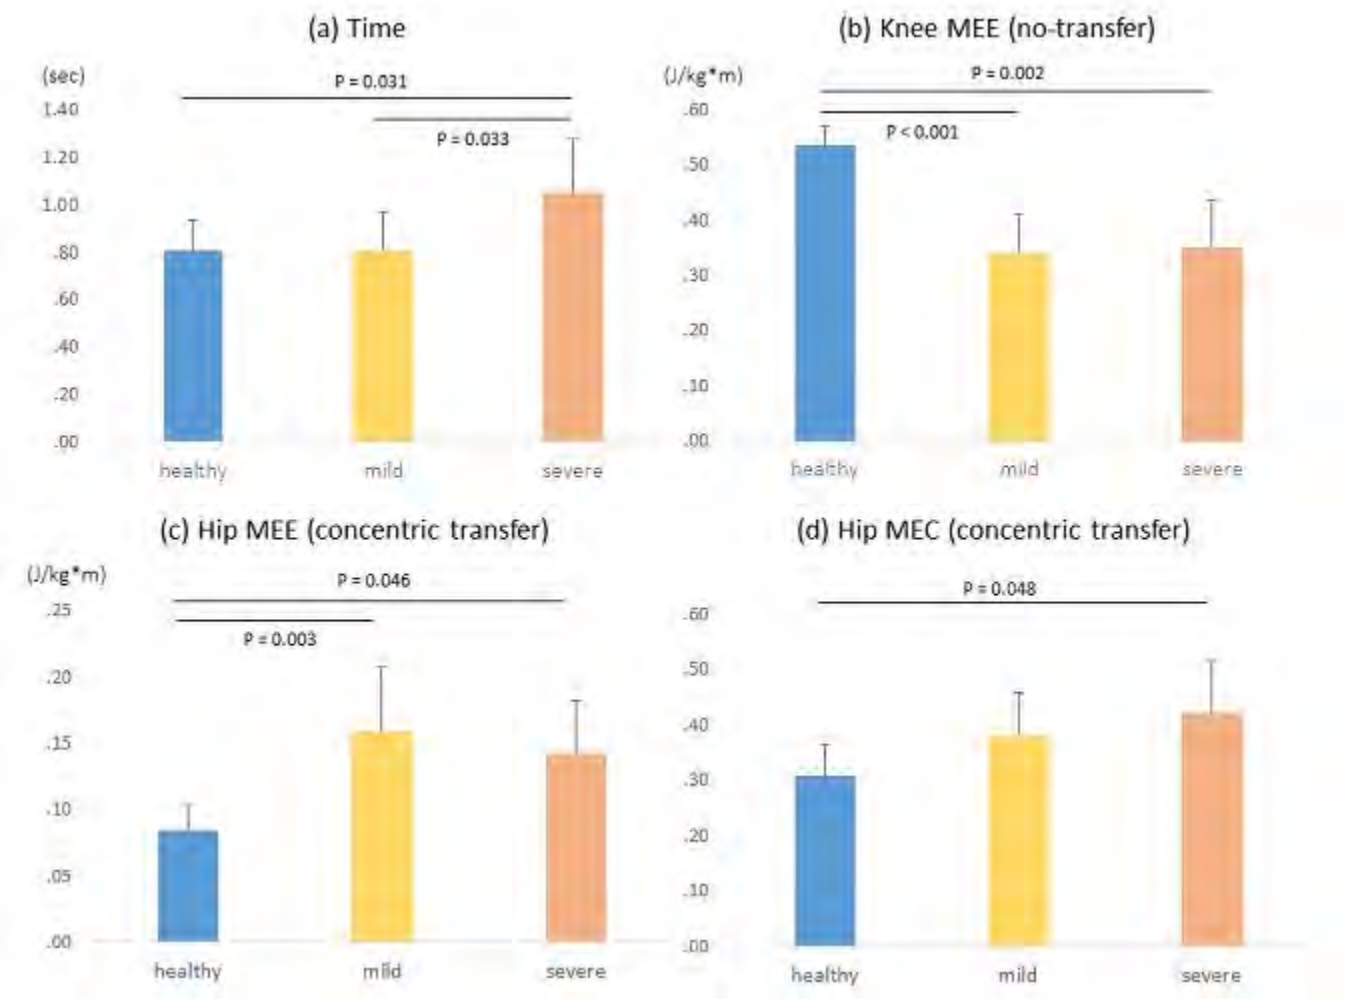
Methods: Twenty-one females with medial knee OA (age: 64.8±7.8years, height: 154.9±3.4cm, weight: 59.7±6.6kg) and six young heathy volunteers (age: 23.8±1.0years, height: 162.7±6.2cm, weight: 55.4±5.3kg)were included in this study. Patients were classified into two groups based on Kellgren-Lawrence grade, with eleven patients allocated to the mild group and the others allocated to the severe group. Each participant was instructed to ascend a 20cm-hight step by the involved limb, that is the more affected side in patients with knee OA and the dominant side in healthy volunteers. Three trials per participant were analyzed with 3D motion analysis system (Vicon Nexus; Vicon Motion Systems Ltd., Oxford, England) and force platforms (Kistler Japan Co., Ltd. Tokyo, Japan). All participants performed these trials in their self-selected speed without using any walking aids.

Data processing was conducted for the period from the timing when the involved limb touched down on the step to the timing when the center of body mass (CoM) reached highest position during single limb stance. Segmental power was calculated at the pelvis, femur, shank, and foot segment of involved limb, and net joint power at each joint of the involved limb was also collected. All kinetic data were normalized to body mass and height of each participant. Mechanical Energy Expenditure (MEE) and Mechanical Energy Compensation (MEC) were determined at each joint by the method described previously [1]. MEE was calculated by the integral of net joint power curve at each joint, and MEC was defined as the proportion of muscle energy compensated by inter-segmental energy transfer. MEE and MEC were determined separately in three phases, according to the previous study [1], as follows ； concentric transfer phase, eccentric transfer phase, and no-transfer phase. Wilcoxon rank-sum test was applied to compare MEE and MEC at each phase and joint between each pair from three groups. The time taken for ascending a step were also compared between each group. Holm correction was applied to take into account multiple comparison. The significance level was set at 5%.

Results: Healthy and mild groups could climb the step faster than severe group, while there were no significant difference between healthy and mild group (Figure (a)). Healthy group performed stair ascending with higher MEE at the knee during non-transfer phase, which corresponds to the phase when the CoM was steadily elevated, compared to both patient groups (Figure (b)). It was also shown that both patient groups ascended with higher MEE at the hip during concentric transfer phase, which corresponds to the phase when the CoM starts rising, compared to healthy group (Figure (c)).

Increased hip MEC during this phase was observed in severe group in comparison to that observed in healthy group (Figure (d)). There were no significant differences in any other parameters between any pairs.

Figure:



Caption: Comparison of (a) time taken for ascending a step, (b) mechanical energy expenditure at the knee during no-transfer phase, (c) mechanical energy expenditure at the hip during concentric transfer phase, and (d) mechanical energy compensation at the hip during concentric transfer phase between each pair from three groups

Conclusion: Though patients with knee OA have difficulties in stair ascending, most them manage to do it with certain compensatory strategies. This study clarified that patients with knee OA generated much mechanical energy at the hip instead of the less energy generated at the knee when they elevated their body to the upper step. It is also suggested that severe OA patients transferred much mechanical energy generated at hip into the femur segment in order to compensate for the less energy generated at the knee.

BIOMECHANICAL ASSESSMENT OF CONGENITAL TALIPES EQUINOVARUS WITH AN ALTERNANT CORRECTIVE METHOD

Wei Chen [1,*] Fang Pu [1] Yang Yang [1] Yubo Fan** [1 2] Hong Liu [3]

[1]Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, International Research Center for Implantable and Interventional Medical Devices, School of Biological Science and Medical Engineering, Beihang University, [2]National Research Center for Rehabilitation Technical Aids, [3]Rokab Pedorthic Center, Beijing, China

Introduction and Objectives: Congenital talipes equinovarus (CTEV) is a common foot deformity, with the behavior of equinus, varus, cavus and adductus[1]. Many children present with obvious forefoot adduction deformity by using the previous corrective methods after they begin to walk. The objective was to introduce a new corrective method which consist of day use and night use orthopedic shoes, and explore the effect of this new correction manner on the outcome for CTEV children.

Methods: 18 CTEV children with moderate grade according to the Dime´glio classification were recruited to have the alternant correct method when they began to walk. Orthopedic shoes were applied for day use and Forefoot abduct shoes (FAS) which especially designed to correct forefoot adduction were applied for night use. The corrective treatment were last for 3-4 years with regularly follow-up visit. A 3D scanner and a high resolution pedobarograph were used to record morphological characteristics and plantar pressure distribution. The value of bean-shape ratio, bimalleolar angle and pressure ratio were analyzed.

Results: The average bimalleolar angle is 77.55 with the range from 75.57 to 79.53. The average bean-shape ration is 0.27 with the range from 0.25 to 0.28. The average heel/forefoot pressure ratio is 0.73 with the rang from 0.61 to 0.86. The average heel/lateral arch pressure ratio is 1.98 with the range from 1.68 to 2.29.

Conclusion: This alternate corrective method can effectively improve forefoot adduction for children with CTEV. In addition, this corrective method could also correct equinus and varus. CTEV children with this alternate corrective method obtain better corrective outcome in clinic and their parents were satisfied with the corrective outcome. PO-0185

PATTERNS OF ACTIVATION OF THE CORE MUSCLES DURING DIFFERENT INTERMEDIATE EXERCISES FROM MAT PILATES IN HEALTHY INDIVIDUALS

Ivye L. Pereira [1,*] Bergson Queiroz [1] Isabel Sacco [1]

[1] Pysiotherapy, Speech Therapy and Occupational Therapy Department, Universidade de Sao Paulo, sao paulo, Brazil

Introduction and Objectives: The Pilates method is an exercises repertoire that aims to improve body awareness, control of movement and posture(1). In chronic low back pain treatment a range of therapeutic possibilities are considered as possible massage therapy, acupuncture, physical therapy (2), yoga (3), and Pilates (4). Pilates has been frequently prescribed for patients with low back pain, due to its central focus on the training of the lumbopelvic stabilizing muscles.The goal of this study is to describe and compare the core muscles electromyographic pattern during intermediate Mat Pilates exercises.

Methods: We performed an electromyography analysis assessing the multifidus, external oblique, internal oblique and rectus abdominis muscles during adapted intermediary exercises of the Pilates classical repertoire (Single leg stretch, Criss-cross and Dead bug). Nineteen healthy subjects (28.1 ± 8.2 years old; 64.5 ± 10.2 kg; 1.60 ± 0.91 m), performed each exercise 6 times. The EMG was acquired unilaterally on the right side of the body and the signal was synchronized with electrogoniometric data placed on the hip. The frequency of sampling was 2000Hz and the raw EMG signals were filtered with the digital band-pass filter Butterworth 4th order with frequency 10-500 Hz. For each movement cycle (lower limb flexion+extension) and for each muscle, the root mean square (RMS) was calculated, normalized by maximum voluntary isometric contraction(MVIC) of each individual and muscle. EMG linear envelopes normalized by the MVIC were calculated to obtain temporal pattern of activation during the exercise cycle. From the linear envelopes, we calculated the peak of activation of each muscle and the time of the peak activation in the exercise cycle.

Results: The magnitude of the muscle activity (RMS and peak activation) showed to be higher in the Criss-cross exercise, followed by the Single Leg Stretch and Dead bug, respectively. Thus, despite the exercises are classified as intermediary, they have different activation patterns.Criss-cross exercise can be suitable to strengthen the obliques muscles and rectus abdominis in healthy people, the Single Leg Stretch promoted gain of strength of the three muscles working during its performance and the Dead bug exercise would favour the stability ability of the rectus and obliques strengthening.The time of peak activation of the external oblique and rectus abdominis showed to be anticipated for the Dead bug and Single leg stretch, compared to the Criss-cross. This result reinforces that Dead bug exercise would be best for early stages of treatment and, as treatment progress, one can introduce the Single Leg Stretch and then Criss-cross in a more advanced stage.

Figure:

Caption: Sequential performance of Single let Stretch (A), Criss-Cross (B) and Dead Bug (C) exercises.

Conclusion: We conclude that the three Mat exercises presented different patterns of activation in terms of magnitude and timing of EMG peak, even with the same classification in the Pilates method, as intermediate exercises, and in terms of treatment progression, we may start with the least challenging exercises (Dead bug, Single leg stretch) and only then progress to more complex exercises that require greater lumbopelvic stabilization (Criss-cross). The Pilates method allowed the activation of the lumbopelvic stabilizing muscles even in a first session, and may therefore be indicated in cases of chronic nonspecific low back pain rehabilitation with proper progression.

SHAPE AND MOBILITY OF RIBCAGE IN CHILDREN WITH HEMIPLEGIC CEREBRAL PALSY

Raquel P. Carvalho [1,*] Ricardo Machado Leite Barros [2] Soraia Libório Cabó [1]

[1]Human Movement Science, Federal University of Sao Paulo, Santos, [2]Laboratory for Instrumentation for Biomechanics, Campinas State University, Campinas, Brazil

Introduction and Objectives: Cerebral palsy (CP) refers to a group of permanent disorders due to a non-progressive disturbance during the process of brain maturation[1]. Children with CP have predominant motor impairment, with different degrees of trunk control and level of functionality. The respiratory system is influenced by disturbances of tone, posture and movement[2]. CP children with severe impairment show lower tidal volume, forced vital capacity and diaphragm movement[3]. This lower respiratory capacity in severe CP is also related to ribs, vertebrae and sternum deformities, and muscle weakness[4]. There are few evidences about ribcage shape and mobility, and if ribs motion is influenced by CP in children with mild impairments like hemiparetic CP children. This knowledge will enable to verify changes on the normal patterns of trunk deformations during tidal capacity breathing in mild CP children. The purpose of this study was to analyze the shape and mobility of thoracic cage in children with mild CP during quiet breathing.

Methods: Eighteen children aged from 8 to14 years old participated of this cross-sectional study. Nine children with spastic hemiparetic CP (levels I and II of the Gross Motor Function Classification System) were included in the group of CP (CPG) and paired by age and gender with nine children with typical motor development who were included in the control group (CG). A three-dimensional kinematic analysis system (Dvideow) with six video cameras was used to describe spatial trajectories of 60 markers attached on anatomical landmarks[5]. The children remained seated on a chair without back support, with abduction of shoulders, knee flexion and feet on the ground. They were asked to avoid any movement while performing quiet breathing during 20 seconds. The linear distances between the markers on the lateral extremities of each right and left rib and between the markers on the thoracic vertebrae and on the sternum were calculated. The experimental variables obtained for the first to tenth ribs were anteroposterior (APD) and transverse diameters (TD). T-Student tests and boxplot analyzes were performed to compare CG and CPG and the lower and higher ribs for each group. This study was approved by the Federal University of São Paulo Ethics Research Committee (nº 275.276). The parents gave permission for the participation of infants in the study by signing a consent form.

Results: There were no significant differences among CG and CPG for mean of APD and TD from the first to tenth ribs, showing similar ribcage shape (table 1). CG and CPG showed higher APD than TD in first, second and third ribs and equal APD and TD in inferior thorax. For CG, the mean of APD increased from first to fifth rib and remained a plateau from sixth to tenth rib. The mean of APD of the first and second ribs were lower than sixth to tenth ribs. The mean of TD increased from first to sixth rib and remained a plateau from seventh to tenth rib. The TD of first, second and third ribs were lower than fifth to tenth ribs. For CPG, the mean of APD increased from the first to sixth rib and remained a plateau from seventh to tenth rib, similar to GC. The mean of APD of first rib was lower than third to tenth rib; the second rib was lower than fourth to tenth rib; and third rib was lower than sixth and seventh ribs. The mean of TD increased from the first to fifth rib and remained a plateau from sixth to tenth rib. The TD of first, second and third ribs were lower than fifth to

tenth ribs, similar to GC. Therefore, both groups showed lower mean of APD and TD in superior than inferior thorax. In relation to mobility, there was no difference among CG and CPG for APD. CPG showed lower absolute variation for fifth, eighth, ninth and tenth ribs for TD.

Conclusion: Children with mild hemiparetic CP showed similar ribcage and lower mobility in lower ribs when compared to typical developmental children. For future researches we suggest to analyze forced breathing to verify possible respiratory dysfunctions during active tasks.

Table:

Group	CG	CPG	CG	CPG
Ribs	**APD(SD)**	**APD(SD)**	**TD(SD)**	**TD(SD)**
1st	14,4(2,1)	14,3(3,6)	10,3(1,0)	11,3(0,7)

PO-0187

A METHOD FOR QUANTIFYING HEEL PAD VISCO-ELASTIC REACTION MODEL PARAMETERS

Roozbeh Naemi [1,*] Panagiotis Chatzistergos [1] Nachiappan Chockalingam [1]

[1]Centre for Sport Health and Exercise Research, Faculty of Health Sciences, Staffordshire University, Stoke on Trent , United Kingdom

Introduction and Objectives: Heel pad represents a shock attenuating interface underneath the calcaneus with a structure of fatty tissue separated by septa (1).This gives the heel pad a unique capacity to attenuate the impact during heel strike(2,3).As the mechanical properties of this interface affect the loading on the entire body(4), the mathematical models that describe force-deformation relationship of the heel pad are used to determine loading on the musculo-skeletal system. While some models only considered the stiffness of the heel pad(5,6)a number of models considered both elasticity and viscosity(7,8,9)to reflect the visco-elastic behaviour of the heel pad. From these models, non-linear visco-elastic model proposed by Scott and Winter(10)proved to adequately represent the plantar fat pad reaction force-deformation relationship(7).Despite this there has been no set method for quantifying the subject-specific model parameters. The objective of this study was to develop a method of quantifying the nonlinear visco-elastic behaviour of the heel pad under load.

Methods: A customised ultrasound indentation device comprising a18 MHz Esaote linear array ultrasound probe connected in series with a 3kN INSTRON load cell was used to extract force deformation data during a compression loading cycle.During loading the instrumented probe was pressed against the plantar aspect of the heel through which the heel pad was compressed between the probe and the calcaneus.

The synchronised force-deformation data was collected at 28 Hz over 10 load/unload cycles at constant target deformation rate of 1.25 mm/s with the actual deformation rate was 0.96 mm/sec ± 0.14 mm/sec. The target stress was 150 kPa, and the first seven load cycles were used for pre-conditioning and the last three were recorded for assessment. The stress-strain data was deducted by normalising the force deformation data to contact area (3.8 cm2 as the probe footprint-area) and the initial heel pad thickness. 9th order Polynomials were fitted to the 3 stress-strain curves during loading and unloading separately. These two loading and unloading polynomials were used to reconstruct the stress during loading and unloading for strains from 0 up to 0.5 strain with 0.01 increment.

In a visco-elastic model that consists of a nonlinear spring parallel to a nonlinear damper (15) during loading the spring and damper both resist deformation (Equation 1).

$\sigma l = a.\varepsilon b + c.\varepsilon d.\varepsilon$. Equation 1

While during unloading the spring works in favour of and damper resists rebound (Equation 2), the parametric elastic and viscous stress components were deducted.

$\sigma u = a.\varepsilon b - c.\varepsilon d.\varepsilon$. Equation 2

The elastic component can be deducted by adding the two sides of equations 1 and 2 as follows:

$(\sigma l + \sigma u)/2 = a.\varepsilon b$ Equation 3

By fitting a power function to the average of stress during loading and unloading parameters a and b were calculated.

The viscous component can be deducted by subtracting the two sides of equations 1 and 2 as follows:

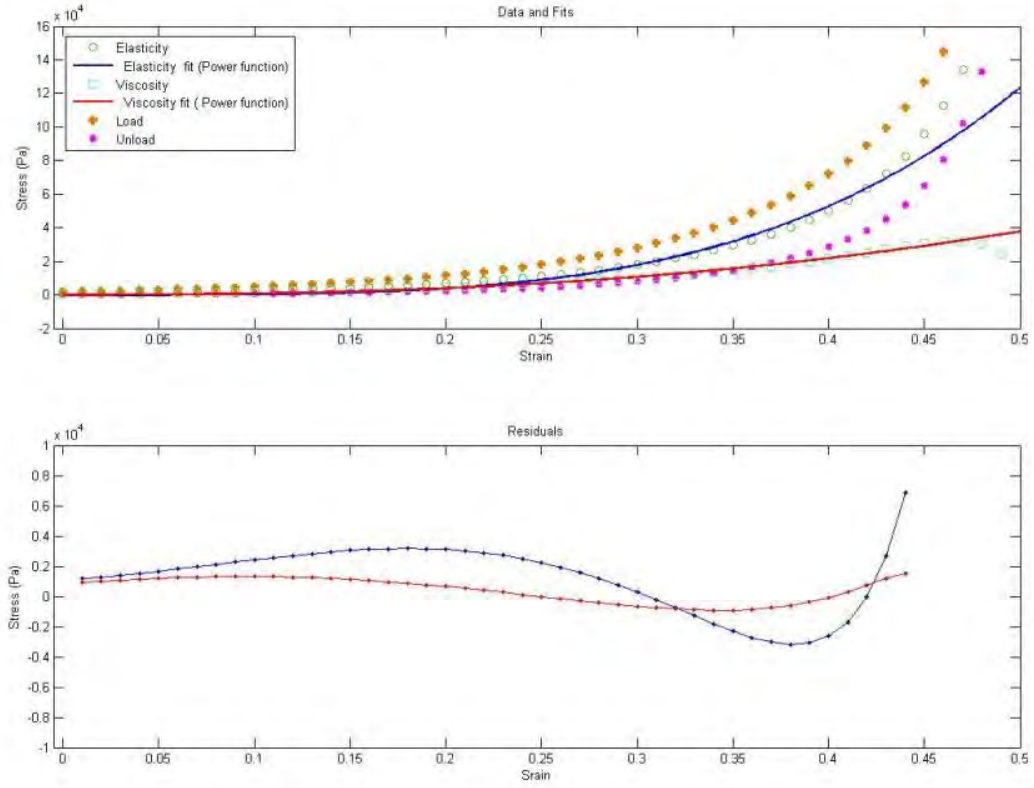
$(\sigma l - \sigma u)/(2.\ \varepsilon.) = c.\varepsilon d$ Equation 4

By fitting a power function to the difference in stress during loading and unloading over twice strain rate parameters c and d were calculated.

Curve fitting was performed using a bisquare method that minimises the summed square of the residuals and downweight outliers (Matlab, Mathworks, 2010). The fit goodness statistics were calculated using R-square and RMSE.

Results: The strain rate was calculated as 0.051 s^{-1} , the elastic scaling factor (*a*) was 1.719 MPa and the elastic exponent (*b*) was 3.801 . The elasticity power function provided a good fit to the elastic stress-strain data with R^2=0.985, RMSE = 2569Pa.The viscous scaling factor (*c*) viscous exponent (*d*) were found as 4.117 MPa.s and 2.477 . The viscosity power function provided a good fit to the elastic stress-strain data with R^2 = 0.9866 and RMSE = 934 Pa .

Figure:



Caption: Top: Loading and unloading data together with the elasticity and viscosity components and the corresponding power function fits.

Conclusion: The proposed method allowed differentiating between the elastic and viscous components of the heel pad response to loading. The curves that represent the elasticity and viscosity functions provided a good fit to the elastic and viscous stress components which indicate that the model can adequately reflect the corresponding stress-strain of the plantar soft tissue during loading and unloading. This method has potential implications in quantifying the mechanical behaviour of the heel pad and can provide a detailed understanding of plantar soft tissue behaviour under load.

RELATIVE EXCURSION OF FLEXOR DIGITORUM SUPERFICIALIS AND PROFUNDUS TENDONS DURING TENDON GLIDING EXERCISE AND FIST

Hsiao-Feng Chieh [1,*] Chien-Ju Lin [2] Li-Chieh Kuo [3] Shu-Chi Liu [1] I-Ming Jou [4] Fong-Chin Su [1 2 5]

[1]Department of Biomedical Engineering, [2]Musculoskeletal Research Center, [3]Department of Occupational Therapy, [4]Department of Orthopedics, [5]Medical Device Innovation Center, National Cheng Kung University, Tainan City, Taiwan, Republic of China

Introduction and Objectives: Adhesion formation following surgery is demonstrated to reduce the normal gliding function of tendons and nerves, causing nerve compression and impairing motion. Recently, adhesion prevention has been paid more attention and indicated as the need for early post-operative mobilization of digits after tendon injury or repair. Several strategies including physical, surgical, and pharmacological treatments have been explored in order to reduce peritendinous adhesion and achieve a better gliding function of the digital tendons [1]. It is generally accepted that tendon excursion could avoid adhesion; however, current knowledge of the rehabilitation protocol is mostly focused on the total tendon excursion [2]. Therefore, the purpose of the current study was to evaluate rehabilitation protocols, tendon gliding exercise and full fist motion, on the total tendon excursion and the relative motion between flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) using high-resolution ultrasound images.

Methods: Ten healthy subjects (5 male, 5 female) with a mean age of 25.2 ± 3.3 years were recruited in this study. Each participant was asked to sit beside the custom forearm clamp, and then eleven reflective markers with a diameter of 2 mm were set on the dorsal surface of the middle digit. The motion of flexor tendon gliding exercises is to posture hand sequentially with straight, duck, straight fist, full fist, and hook. Fist motion is from straight to full fist and then from full fist to straight. The Images of tendon movement and finger motion were acquired by an ultrasound scanner (S2000, SIEMENS) and motion capture system (Motion Analysis Corporation), respectively. Manual tracking was used to measure the excursion of the FDS and FDP tendons. All tests repeated 3 times for both FDS and FDP tendons.

The tendon excursions during motion were measured and correlated with the corresponding finger joint angles. In order to identify the characteristic pattern during different motion, the process of tendon gliding exercise was divided into five phases, straight-duck (Phase I), duck-straight fist (Phase II), straight fist-full fist (Phase III), full fist-hook (Phase IV), and hook-straight (Phase V). Meanwhile, the process of active fist motion was divided into five phases according to the corresponding total joint angle in the tendon gliding exercise. Tendon excursions of FDP and FDS were measured and the normalized relative tendon excursion between FDP and FDS were calculated during the whole movement and individual phases. The calculation of normalized relative tendon excursion (R_d) is shown as follows,

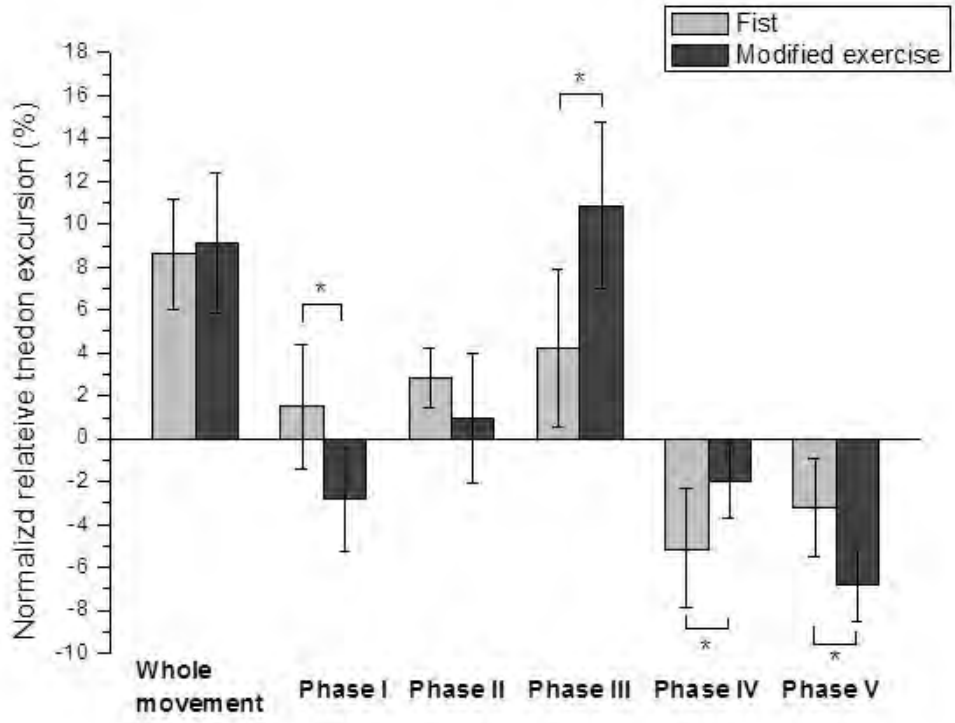
$R_d = [(E_{FDP} - E_{FDS})/\text{Hand Length}]x100\%$

where E_{FDP} and E_{FDS} are the excursions of FDP and FDS, respectively.

The maximum tendon excursion and the normalized relative tendon excursion for both motions were compared using a paired t-test (SPSS 17, SPSS Inc., Chicago, IL). $p \leq 0.05$ were considered statistically significant.

Results: Results showed that the total tendon excursion of FDP and FDS during fist were 40.23±5.29 and 24.69±2.83 mm, respectively. During modified exercise, the total tendon excursion of FDP and FDS tendons were 40.04±6.11 and 23.64±2.74 mm, respectively. Our statistical analysis indicated that the maximum FPS excursion, maximum FDP excursion, and the maximum relative excursion of FDP and FDS between two motions showed no significant difference. In this study, the gliding process of tendons was analyzed to distinguish the relative motion of tendons. Results showed the greater normalized relative motions between FDP and FDS during phase I, Phase III, and Phase V during the modified exercise than that during pure fist motion (Figure 1). Furthermore, the greater difference between two continuous phases during the modified exercise demonstrated the greater relative motion between tendons and showed a higher potential for adhesion prevention.

Figure:



Caption: Normalized relative tendon excursions between tendons during whole movements and individual phases.

Conclusion: Our findings demonstrated that the modified tendon gliding exercise could achieve a better solution of adhesion prevention than pure fist motion. These data suggested that in addition to the total tendon excursion, the relative tendon motion during the process should be taken into account while evaluating the efficacy of rehabilitation protocols.

GROWING LOW COST BACTERIAL CELLULOSE – THE LUMPS MATTER

Nicola Everitt [1] Christopher Mariani [1] Donal McNally [1,*]

[1] Faculty of Engineering, University of Nottingham, Nottingham, United Kingdom

Introduction and Objectives: Bacterial cellulose has been the subject of a great deal of research since 1989, when the first research was published on a pellicle from Acetobacter Aceti [1]. The high mechanical properties observed on sheets of cellulose prepared by the bacteria has attracted the attention of a variety of different research fields including its use as an artificial medical tissue such as scaffolding for the tissue engineering of cartilage[2].

The objective of this study was to produce cellulose sheets using a low cost water bath culture and air dry method, mechanically characterise them and relate the behaviour to the observed microstructure.

Methods: Gluconacetobacter xylinum ATCC®700178 was initially provided by Dr. Stuart Thompson at the University of Westminster. 100 ml of fresh culture medium was inoculated with 1ml of seed bacteria. The bacteria were statically cultured in a water bath at 27°C, without any disruption. After 9 to 12 days the pellicles were harvested from the culture, washed with distilled water and then were stored under refrigeration, floating in distilled water. Harvested pellicles had a diameter of 75 mm and a thickness of approximately 0.5 mm. Test samples were produced by cutting into strips 5 mm wide and 30 mm long. The samples were air dried for 48 hrs between filter papers, with a steel mesh and then a mass on top (applying a pressure of ~5 MPa).

Tensile testing was conducted using a Deben Microtest 200 machine with a 200 N load cell. The tests were conducted at an extension rate of 0.2 mm/min.

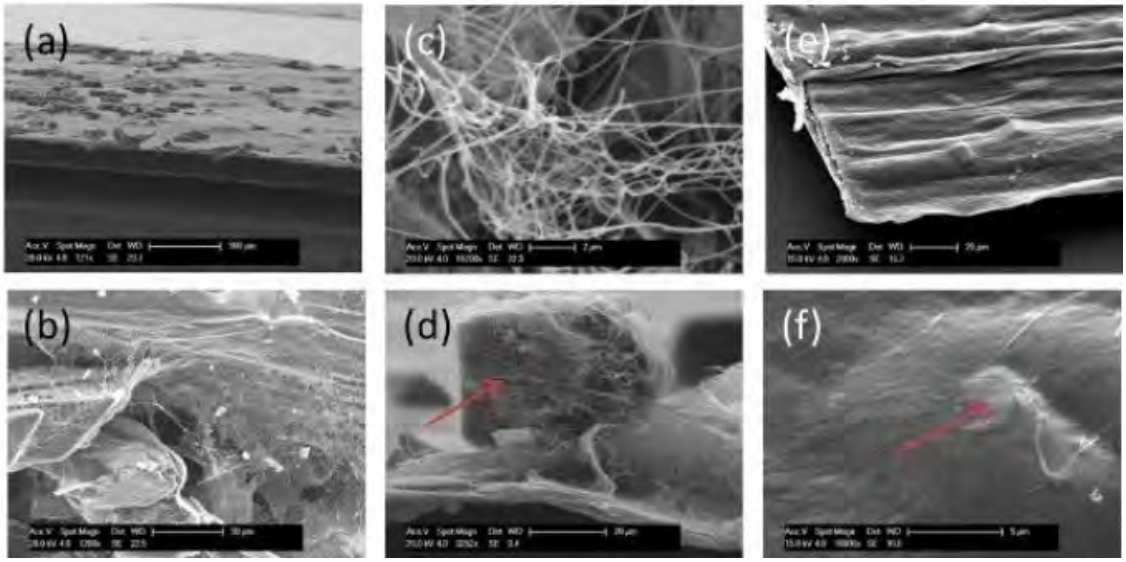
Results: 7 of the 12 (58%) cultures carried out produced pellicles, of which 5 produced a useable pellicle, giving an overall success rate of 42%. Reasons for a pellicle not being produced included culture infection and bacterial mutation.

Analysis of scanning electron microscopy (SEM) images showed the pellicles were comprised of randomly distributed cellulose microfibrils (Fig 1), as expected from previous studies. Using Environmental SEM the fibril diameter was measured at between 90 - 110nm. This agrees with previously published data measuring the diameter of fibrils to be less than 130nm [1].

Figure 1 (a and b), shows large scale crystal formation formed throughout the sample. Figure 1(d) shows the size of the crystal in comparison to the cellulose sheet clearly. The crystal measured 36 μm compared to the sheet thickness of 5.7 μm. The crystal formation causes significant disruption to the fibril network. The crystals have grown from within layers of fibrils and forced the fibrils away from the main plane. Broken fibrils can also be seen. The corners of the crystals will also act as stress concentration sites across the sheet, further reducing the tensile stress the sheet can withstand as well as the fibrils mobility in the structure. More vigorous washing saw a reduction in crystal formation during the air drying, with a much smoother and flatter sheet produced Fig 1(e and f). Figure 1(f) shows how the crystals were forming from within the sheet and not on the surface. The crystals were still present but were much smaller, at approximately 5 um, and no longer breaking the surface of the sheet and breaking fibrils.

The stress strain curves for the bacterial cellulose were what would be expected from their structure. Namely a region of relatively low stiffness as the fibrils move over one another and align to the stress, followed by a stiffer region as the fibrils are loaded to failure. The mechanical properties of the samples from pellicles A and B are presented in Table 1. The strength and stiffness of the two pellicles are significantly different ($p>0.95$), demonstrating that the crystals in the structure cause significant deterioration in the mechanical properties.

Figure:



Caption: Figure 1 – Scanning electron micrographs of dried cellulose sheets. Pellicle A (a-d). (a) crystal formation on the surface, (b) crystal disruption of the fibril network, (c) amorphous fibril network, (d) crystal size in relation to cellulose sheet thickness. Pellicle B (e-f). (e) sheet, (f) crystal within the structure. Red arrows indicate crystals.

Conclusion: The water bath culturing method selected for the project was driven by cost and availability. The water bath method provided a low initial cost route to culturing the bacteria but infection is higher than incubator culture. The mechanical properties, whilst lower than other methods of production, are appropriate to musculoskeletal soft tissue. Crystal formation in the cellulose structure has proven to be extremely damaging to the mechanical properties.

Table:

Pellicle	Ultimate tensile strength (MPa)	Strain to failure (%)	Young's modulus (GPa)
A	12.4	0.43	2.96
B	68.8	1.27	6.26

BIOMECHANICAL PROPERTIES OF RAT CERVIX IN THE LAST TRIMESTER OF PREGNANCY

Alireza Ashofteh Yazdi [1,*] Ali Esteki [2] Mohammad Mehdi Dehghan [3] Farhad Tabatabai Ghomsheh [4]

[1]Department of Biomechanics, Science and Research Branch, Islamic Azad University, Tehran, Iran, [2]Department of Biomedical Engineering, Shahid Beheshti University of Medical Sciences, Tehran, Iran, [3]Department of Veterinary Surgery, University of Tehran, Tehran, Iran, [4]Department of Ergonomics, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran, Islamic Republic Of

Introduction and Objectives: Cervical Insufficiency refers to a condition in which the cervix dilates in the absence of contractions from the uterine smooth muscles and results in a spontaneous pregnancy loss between the second and third trimester of pregnancy [1]. Quantitative measurements of its mechanical properties may lead to a more accurate description of cervical remodeling and prediction of preterm birth [2]. The results of this research provides an insight to the stiffness of the pregnant cervix and allows us to investigate the mechanical changes that lead to a premature delivery in the beginning of the last trimester of pregnancy.

Methods: Cervices were harvested from Wistar rats early in the last trimester of pregnancy (15-17 days). The distal halves were taken immediately to the laboratory for mechanical testing. Samples were subjected to a series of tensile, cyclic and relaxation tests to measure both linear and nonlinear mechanical properties of the pregnant tissues. Strain controlled tensile loadings were implemented to the samples in the circumferential direction. In the tensile test, tissue was stretched at the rate of 0.01 mm/sec to the rupture point. In cyclic test, tissue underwent 10 cycles of loading and unloading at the rate of 1 mm/sec up to 60% strain. The relaxation test was fulfilled at the rate of 0.01 mm/sec up to 60% strain and was held for 10 minutes untill the tissue relaxed. Stress and strain were measured as functions of time and curve fitting tool in Matlab was used to model the results.

Results: Tensile linear results revealed a Young's modulus of 0.014 MPa, as well as an ultimate stress and strain of 0.3 MPa and 79.9%, respectively. Failure stress and strain was measured as 0.085 MPa and 190.1%. Cyclic and Relaxation tests indicated a nonlinear, time-dependent behavior of tissue with a large range of plastic deformation in the last trimester of pregnancy.

Conclusion: According to previous studies [2, 3], Cervix becomes more compliant as compared to the former two trimesters and virgin ones. This is related to the nonlinear viscoelastic behavior of the pregnant tissue which is due to its compositional and microstructural changes in the last trimester of pregnancy.

PO-0191

MECHANICAL STRAIN REQUIREMENT FOR SUCCESSFUL DECELLULARISATION OF PORCINE BLADDER

Ashley Ward [1,*] Jen Edwards [1] John Fisher [2] Jenny Southgate [3] Helen Berry [4] Eileen Ingham [1]

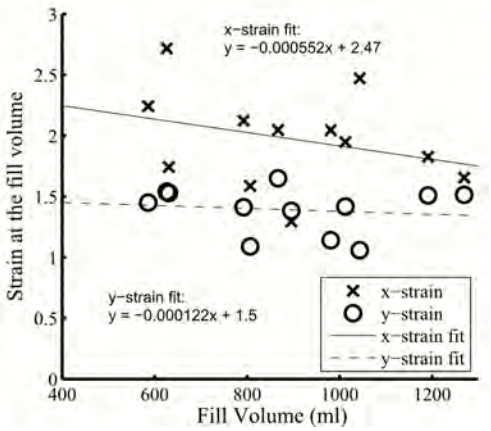
[1]School of Biomedical Sciences, [2]Institute of Medical and Biological Engineering, University of Leeds, Leeds, [3]Department of Biology, University of York, [4]Tissue Regenix, York, United Kingdom

Introduction and Objectives: Current surgical bladder augmentation procedures have limitations [1]. A decellularised xenogeneic bladder biomaterial may have utility as an augmentation device. Previously, a process was developed for porcine bladders that required bladders to be distended to achieve successful decellularisation [2]. This process was found to be incompatible with scalable manufacturing processes. This project aims to develop a new process for the decellularisation of porcine bladder which avoids distending intact bladders, for translation to commercial manufacture.

Methods: Two porcine bladders were decellularised using low concentration SDS and proteinase inhibitors as described previously [2]. Throughout the process each bladder was distended with 500 ml of solution. Bladder filling experiments were carried out on fresh bladders in order to find a relationship between required bladder fill volumes and initial bladder dimensions. Bladder decellularisation was repeated using these fill volumes, rather than the 500 ml volume specified by the original process. In order to determine the state of deformation in the bladder walls when bladders were successfully decellularised, bladders (n = 12) were immersed in and distended with PBS at the required volumes. Volume, pressure, strain and stress were measured and calculated throughout the distension process.

Results: One of the bladders decellularised using the original process, which was considerably larger than usual, was not fully decellularised. The filling experiments then established a relationship between the initial dimensions of bladders and their fill volumes. Bladders decellularised using these revised fill volumes were successfully decellularised, and all were filled with volumes larger than 500 ml during the process. When bladders were immersed and distended, the strains in the bladder walls at the calculated fill volumes were found to be 1.97 ± 0.11 and 1.39 ± 0.06 [Figure 1] in the transverse and apex-to-base directions respectively (mean ± standard error of the mean). The pressures and stresses in bladders at the fill volumes were highly variable.

Figure:



Caption: The wall strain of bladders filled to their fill volumes. Strain at the fill volume does not vary substantially with fill volume.

Conclusion: Bladders decellularised using the modified fill volumes were acellular. The strains found in distended bladders that resulted in successful decellularisation will now be applied to flat sheets of porcine bladder tissue as part of a decellularisation manufacturing process.

COMPARISON OF NAVIGATED TOTAL KNEE REPLACEMENT INTRA-OPERATIVE COMPUTER GENERATED DATA WITH ACTUAL PATIENT ANATOMY

C Govind [1,*] A H Deakin [1 2] P E Riches [1] F Picard [1 2]

[1]Faculty of Biomedical Engineering, University of Strathclyde, Glasgow, [2]Department of Orthopaedics, Golden Jubilee National Hospital, Clydebank, United Kingdom

Introduction and Objectives: Failure to correct lower limb alignment in total knee replacement (TKR) is known to increase the risk of implant failure [1]. The use of computer navigation systems in TKR is reported to reduce the number of outliers for coronal lower limb alignment [2]. These navigation techniques determine hip, knee, and ankle centres and then establish the mechanical axes between them and provide this information to the surgeon. Based on this virtual lower limb model the position and orientation of resections can then be calculated. For these computer models to be accurate the patient anatomy must be properly defined. This project aimed to compare the location of anatomical and kinematic points as calculated by navigation software to anatomical points in a CT scan.

Methods: This retrospective study was approved by an NHS Research Ethics Committee and all patients consented to the use of their data. Data from 21 navigated TKRs (OrthoPilot, Aesculap, Tuttlingen, Germany) were included in the study. For each patient, data on the anatomical and kinematic points were collected from the computer navigation file. Post-operative lower limb CT images were analysed using Mimics (Materialise, Leuven, Belgium) to give the anatomical coordinates of lower limb landmarks and joint centres from the navigation data. The landmarks found in both datasets were the medial and lateral malleolus, the medial and lateral epicondyles, the distal medial and lateral condyles and the hip joint centre. From this information the relative ankle and knee widths and the femoral and tibial lengths were calculated. To determine the relationship between the kinematic and anatomical knee centre, an anatomical knee centre midway between the distal condyles as described by Moreland et al. [3] was used as. A local coordinate system was created from CT and navigation data to enable comparisons. Basic patient demographics were collected. The post- and intra-operative mechanical femorotibial (MFT) angles from both systems were provided as a result of a previous study. Comparisons between the navigation and CT measurements for widths, length and knee centre were made by using two-tailed paired T tests to see which differences were significant. To investigate the influence of patient demographics (BMI and age) on these findings, regression analysis was used.

Results: The kinematic knee centre was on average 34.1± 7mm away from the anatomical centre. The major component being along the longitudinal axis of the leg meaning that the kinematic knee centre was on average 33.8± 7mm proximal to the anatomical. The relative error corresponded to a 12± 2% difference when normalised with respect to CT leg length. No significant changes were present between the ankle widths, knee widths, tibial length and alignment angles. Only the femoral length in both data sets showed any significant difference ($p=0.03$) with the navigation data giving a shorter femur. Overall, there was no statistically significant difference between MFT angle values in the CT and the navigation data ($p=0.182$).The effects of age and BMI had no effect on outcome measures.

Conclusion: To the authors' knowledge this is the first time anatomic and kinematic knee centre data have been compared in osteoarthritic patients.The difference in knee centre position is likely to be a result of the differing definitions of the anatomical knee centre. As the differences in knee centre position along the longitudinal axis were found to be significant, it is likely that this would have a further effect on the femoral length. The consistent difference (12± 2%) between the anatomical and kinematic knee centres facilitates the prediction of the kinematic centre from CT data. The limitations of this study include the small number of subjects, a lack of a pre-operative CT scan which would have allowed more points to be compared and also a lack of known points (fiducials) in the navigation data and CT scans that would have allowed direct comparison of location. We conclude that the navigation system was able to create an appropriate lower limb model. The kinematic knee centre relates well to the anatomical centre in the transverse and sagittal planes although there is a large difference in the coronal plane. Further work would be to assess a larger sample of patients with pre-operative CT scans.

PO-0193

THERMAL DAMAGE DONE TO BONE BY BURRING AND SAWING WITH AND WITHOUT IRRIGATION IN KNEE JOINT REPLACEMENT

G Tawy [1,*] P Rowe [1] P Riches [1]

[1] University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Orthopaedic tools which resect bone in procedures such as total knee replacement (TKR) generate heat, causing a temperature rise at the resected surface1. When bone temperature exceeds 47°C for >60 seconds irreversible changes known as osteonecrosis develop2. Osteonecrosis has been found to increase rates of aseptic implant loosening and implant failure by causing cell death at the cut surface, thus reducing the likelihood of bone-implant incorporation2. With computer assisted surgery becoming more common in orthopaedics, burrs are being increasingly used. This study aimed to compare the traditional oscillating saw to the burr (NavioPFS, Blue Belt Technologies Inc.) in terms of temperature generation, and thermal damage done to bone health. The effectiveness of irrigating bone to reduce bone temperature was also investigated.

Methods: Bovine femora (n=17) were burred and sawed with or without irrigation, and bone temperatures were recorded with a visual infrared thermometer. Two cooling agents were used; one at room temperature, and a second at 4°C. After cutting, samples were removed for histomorphometric analyses. Percentages of non-viable osteocytes at the cut surface were calculated, and minimum depths of thermal damage done by both cutting tools were estimated. Statistical analyses were carried out to test differences between groups ($\alpha = 0.05$).

Results: We found some evidence that burring produced temperatures of >47°C for >60 seconds more often than sawing. The mean and maximum temperatures also tended to be higher when burring. However, there were no statistical differences between the temperatures generated when sawing and burring ($p > 0.05$). Irrigated bone had lower temperatures, higher percentages of viable osteocytes, and smaller thermal damage depths ($p < 0.05$). Uncooled saline was successful at reducing mean temperatures <47°C in sawed bone, however cooled saline was needed when burring ($p < 0.05$).

Conclusion: Temperatures recorded in this study whilst burring and sawing reflected those quoted in similar studies. Despite this, it was not possible to fully reproduce the surgical scenario in the laboratory as no blood supply was present. For this reason the results should be treated with caution when considering resecting bone in theatre. It is believed that uncooled saline was able to lower the temperature of sawed bone to <47°as the irrigation was directly applied to the bone. This was not the case when burring, as the tubing which conveyed the fluids to the cutting site was attached to the drill, which becomes heated with use. This could have increased the temperature of the saline solution, thereby affecting the results, and requiring cooled saline to be used. As expected, lowering the temperature at the cutting site reduced the extent of histological damage done to the bone. Despite these positive results, further research needs to be carried out to determine whether these results are replicated in theatre.

Conclusion: The results suggest that thermal damage is done to bone tissue during surgery, and could be reduced with the use of irrigation (especially cooled saline). This may be most beneficial in procedures which involve implanting

cementless prosthetic parts, where the only heat source comes from the cutting tools. By reducing the level of osteonecrosis, rates of implant loosening and failure could be lowered.

PO-0194

EFFECTS OF ANTENATAL EXERCISE WITH OR WITHOUT BALL ON BACK PAIN AND PERINEUM STATE

LAWANI Mansourou [1,*]DUMAS Geneviève [2]HOUETO Gratien [3]

[1]INJEPS, UAC, PORTO-NOVO, Benin, [2]Mechanical and Materials Engineeringi, Queen's University, Kingston, Canada, [3]Laboratoire de Biomécanique et Performance, INJEPS, PORTO-NOVO, Benin

Introduction and Objectives: Pregnancy is an important period of postural changes in women. Indeed, the spine is subjected to severe physical stresses that alter the normal biomechanics of the body. Several offsets occur due to the change in the body mass and its distribution among pregnant woman. These changes create imbalances in the muscles and ligaments of the back, pelvis and lower limb and changes in the posture of the woman. The prevalence of low back pain during pregnancy varies between 40% and 90%, with an incidence of back pain by 61% [1-3]. This prevalence is 56% among pregnant women in Benin. [4]

During pregnancy, women are looking for natural approaches, different treatments those offered by conventional medicine and remedies that can relieve their back pain [5]. This is what justifies this comparative study of the effects of exercise programs with or without gym ball on back pain and childbirth.

Methods: This study is transversal, analytic and comparative, conducted in 69 pregnant women with back pain who have voluntarily agreed to participate regularly in the execution of training programs. The experiment was conducted over a period of 5 months (February-June 2014). Women were randomly assigned to one of the three groups: 1) no training, 2) training without exercise ball, 3) training with exercise ball?

Ethical considerations : All participants signed an informed consent form. The study was approved by scientific committee of sectorial Sciences and Technics of Physical Activities and Sport of Abomey-Calavi University.

Data analysis : Data were collected before and after the implementation of the different programs, postpartum and recorded on the cards for data collection. These data were then processed with Microsoft Office Excel 2007 software and STATISTICA version 5.5 Stat Soft Inc. For each variable, the mean and standard deviation are calculated. The ANOVA test allowed us to globally compare continuous variables. When the probability is less than 0.05, the final statistical decision is taken on the basis of binary tests. The significance level was set at $p < 0.05$.

Results: The analysis of the results reveals that the lumbar region (69.56 %) is the area most exposed among pregnant women suffering from back pain while the other parts of the body are pelvis (18.84 %), groin (8.69 %) and leg (2.89 %). Significant reduction (50.79 %) of the intensity of pain was noticed among women trained in gymnastics with ball, compared to the other two groups.

Table I show that the majority of women who participated in the study were involved in domestic activities such as sweeping, washing clothes, washing dishes, fetching water and cooking. They cook mostly in sitting position (84.05%), draw water standing (92.85%) and 80.59% of women sweep in bent position. Figure 1 shows that the largest number of intact perineum (20 women on a sample of 23 women or 86.95%) was observed in the group of women trained in prenatal gymnastics with ball against 30.43% for women untrained and 73.91% for women trained in prenatal gymnastics without the ball. Women in the training programs experienced a significant reduction in back pain. These results corroborate

several studies regarding the effect of gymnastic exercise on back pain [6,7]. The ball exercises help prepare the deep muscles, support the lower back and spine so as to have better posture and less subjects with back pain [8]. Regarding the state of the perineum our results corroborate those of Delgado et al. [9].

Figure:

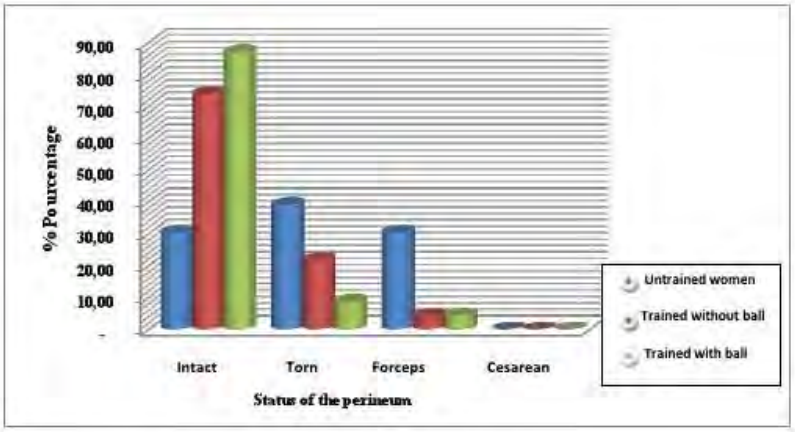

Figure 1 : Status of the perineum after childbirth

Conclusion: Pain decreased significantly in women in the training programs with better advantage among women trained in prenatal gymnastics with ball compared to those trained without the ball. Antenatal gymnastics with ball is an effective way to treat back pain and promotes an uncomplicated delivery.

Table I: Distribution of Women according postures during housework

Computer Simulation

PO-0195

HOW TO GENERATE INJURY PRONE SITUATIONS FOR NONCONTACT ACL INJURIES BY MONTE CARLO SIMULATION

Robert Eberle [1 2,*] Dieter Heinrich [1] Peter Kaps [2] Michael Oberguggenberger [2] Werner Nachbauer [1]

[1]Department of Sport Science, [2]Unit for Engineering Mathematics, Department of Engineering Science, University of Innsbruck, Innsbruck, Austria

Introduction and Objectives: ACL injuries are one of the most common knee injuries in sports. If video sequences of injury situations are available the kinematics can be obtained by video analyses to study injury mechanisms (e.g. [1]). But these video sequences are rare and because of ethical reasons it is not feasible to imitate injury prone situations experimentally. Musculoskeletal computer simulations allow to simulate injury situations on the computer and to predict ACL loads (e.g. [2]). Musculoskeletal simulation models combined with Monte Carlo simulation have been applied successfully. In addition certain injury mechanisms were investigated (e.g. [3]). In these studies Monte Carlo simulation was applied to generate repeated forward dynamic simulations. These approaches neglected the task-oriented adaptive behavior of the athlete. A formulation as optimal control problem allows considering this task. In this work an optimal control problem formulation was applied to generate injury prone situations for ACL injuries by using measured kinematics of a non-injury situation. The approach is demonstrated for jump landing in downhill skiing.

Methods: The musculoskeletal simulation model was written as a system of implicit differential equations [2]

$f(x,x',u)=0$ (1)

with state variables $x=[q,q',L_{CE},a]$ and control variables u. Here, the state variables q, q' denote the generalized coordinates and velocities of the model, L_{CE} denotes the muscle fiber lengths and a the active states of the muscles. A measured reference movement was reproduced by the musculoskeletal simulation model. This was formulated as an optimal control problem. The goal was to minimize an objective function with respect to muscle excitation patterns u:

$J=J_1+J_2+J_3 \rightarrow min$ (2)

subjected to constraints given by equation (1). The objective function J consisted of three terms. The term J_1 was used to fit the generalized coordinates q to data of a measured reference movement, J_2 represented the mean of spared muscle excitations u and J_3 was used to avoid exceeding physiological limits as hyperextension or hyperflexion. Direct collocation was used to transform the optimal control problem in a Nonlinear Programming Problem (NLP), which was solved using IPOPT [4].

Injury prone situations were generated as follows. The initial kinematics of the reproduced reference movement was n times randomly perturbed and the optimal control problem was recomputed. The ACL loads were calculated for all n simulations and the simulations with ACL forces higher than a threshold of 1689 N were collected. The threshold was determined by the 3-sigma rule using measurement data of the maximal traction force of the ACL obtained by Woo et al. [5]. These simulations were classified as injury prone situations.

This approach was applied to generate injury prone landing situations during jump landing in downhill skiing. The data of a non-injury landing situation were taken from Nachbauer et al. [6].

Results: The series of 1500 Monte Carlo simulations results in 527 injury prone landing situations (405 simulations for right ACL, 122 simulations for left ACL). The mean values of trunk orientation and joint angles 100 ms before impact were calculated for the injury prone landing situations. In the injury prone landing situations the skier had compared to the reference jump a more backward trunk orientation, the ski tails impacted first and the skier landed on one leg with a more extended knee.

Conclusion: The presented approach can be used to generate injury prone situations for ACL injuries on the computer using measured kinematics of non-injury situations. The conventional investigations with musculoskeletal simulation models were done by forward simulations and neglected the task-oriented adaptive behavior of the athlete. The formulation as optimal control problem in this work considered this task.

The approach was successfully applied to study jump landing in downhill skiing. The results are consistent with video recordings obtained in Senner [7].

The computer generated injury prone situations can be used to study injury mechanisms or the effects of equipment and muscle parameters on ACL loads during injury prone situations.

NUMERICAL STUDY OF THE ANKLE OSTEOARTHRITIS AFTER ACUTE INVERSION ANKLE SPRAIN ON NORMAL WALKING

Ji Yong Bae [1,*] Kyung Soon Park [2] Jong Keun Seon [2] Gunhee Kim [1] Insu Jeon [3]

[1]Korea Basic Science Institute (KBSI), Center for Analytical Instrumentation Development, Daejeon, [2]The Center for Joint Disease, Hwasun Hospital, Chonnam National University, Hwasun-Gun, Jeonnam, [3]School of Mechanical Engineering, Chonnam National University, Gwangju, Korea, Republic Of

Introduction and Objectives: Ankle sprains are a common musculoskeletal injury in which the ligaments of the ankle partially or completely tear due to sudden stretching. It mainly occurred by an excessive inversion or eversion of ankle joint, and caused a damage of the lateral collateral ligament (LCL), which is consisted of anterior talofibular ligament (ATaF), calcaneofibular ligament (CF) and posterior talofibular ligament (PTaF). Damage of the LCL includes rupture of ATaF or often to the combined with CF. Most treatment for injury of the LCL is performed using conservative methods. However, when adequate treatments are not applied, injury of the LCL can be developed into chronic ankle instability. It induces to the damage of the articular cartilage and finally can be led to osteoarthritis [2]. In present study, three dimensional finite element model of the ankle joint was developed to investigate the causal link between lateral ankle instability and osteoarthritis. Altered kinematics of the ankle joint, contact pressure of articular cartilages and strain pattern of LCL were calculated through finite element analysis using developed finite element model. Based on the results, the causal links between lateral ankle instability and osteoarthritis are clearly elucidated.

Methods: A. 3D reconstruction of the ankle joint

T1 MR images were obtained from healthy left ankle joint of a 33-years-old male in the axial plane at neutral foot position. The MR scan was performed using a 3TMR scanner (Signa Excite 3.0T; GE HealthCare, USA) at intervals of 0.7mm. In order to keeping non weight bearing situation, the volunteer maintained the supine position at least 30 min before scan. The acquisition parameters for the MR scan were determined as a field of views of 250×250 mm, an optimal pixel size of 0.566mm, and a resolution of 512×512. Using obtained MR images, 28 bony structures (including tibia, fibula, talus, calcaneus, cuboid, navicular, cuneiforms, metatarsals and components of the phalanges), their articular cartilges and enveloped soft tissue were 3 dimensionally reconstructed using the commercial software MIMICS (v10.1, Materialise, Belgium).

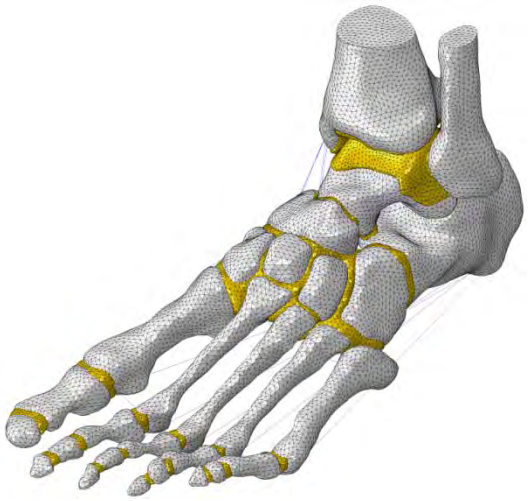
B. Finite element modeling and material properties

Based on the reconstructed ankle joint model, 3D Fe meshes were generated including ligament, tendon and plantar fascia using the commercial software PATRAN (v2008, MSC Software Corporation, USA). The tetrahedral solid element was used for all the bony structure models and cartilages, and the tetrahedral hybrid continuum element, which is suitable for hyperelastic material, was used for the enveloped soft tissue. The bony structures, cartilages and ligaments were assumed to be homogeneous, isotropic and linear elastic material. (5,6) The enveloped soft tissue was considered as 2nd order polynomial hyperelastic model. The ligaments were modeled as 1D truss elements considering a physiological cross

sectional area (PCSA) (Fig.1) [7,8]. Based on the intact model, 3 types of LAI model such as without ATaF, without CF and without both ligaments were developed, and used in our simulations.

Results: Contact pressure and strain on the talus articular cartilage and anteroposterior translation of the talus increased gradually as the walking phase progressed. The values increased rapidly at the push off (PO) stance phase. Peak contact stress and strain and translations were higher in anterior talofibular ligament (ATFL)-deficient models than in the intact ankle joint model at each stance phase, and they were highest in the ruptured LAL models.

Figure:



Caption: 3D FE model of ankle joint without enveloped soft tissue.

Conclusion: The LAL injury increased the contact pressure and strain on the talus articular cartilage and the translations of the talus during normal walking. Therefore, the injured LAL, under normal walking conditions, could be a significant cause of ankle joint osteoarthritis. Ankles with ruptured ATFLs had a higher likelihood of experiencing the osteoarthritis than ATFL laxity ankles. In particular, ankles with ruptured ATFL+calcaneofibular ligament (CFL) and all ruptured ankles had a similar likelihood as the ruptured ATFL ankles. The PO stance phase was the worst situation for ankle joint osteoarthritis in the LAL injury ankles.

PO-0197

MODELLING STERNOTOMY VIA FINITE ELEMENT ANALYSIS

Nicholas Farrugia [1] Kevin Schembri [2] Zdenka Sant [1,*]

[1]Department of Mechanical Engineering, University of Malta, [2]Department of Cardiothoracic Surgery, Mater Dei Hospital, Msida, Malta

Introduction and Objectives: Median sternotomy is a surgical procedure in which access to the vital organs is obtained by sternum dissection. Despite the low occurrence, the postoperative complications are associated with a high mortality rate[1]. Thus the interaction between the suture and the sternum bone requires further studies. The presented work aims to increase this knowledge pool.

Sternal wire fixation is a commonly used technique as it is easier than the rigid-plate technique. Excessive tensioning of the sutures cuts through the bone while lack of tensioning would not promote the bone healing process. Number of tests carried on animal or cadaver bone as well as on the foam model are reported in the literature but none provides analysis of bone-wire interface behaviour[2].

Computational modelling has increased in the past years as it is rapid, provides relative inexpensive evaluation, and reasonable comparison of different closure techniques. Its main drawback is the extent of present knowledge translated in a mathematical model of the bone microstructure into a macrostructure model. Another drawback specific to this approach is the load simulation relying on a mathematical model or experimental data.

The objective of this study was to obtain a stress-strain distribution after median sternotomy using a locally used wire closure technique.

Methods: The three-dimensional sternum geometry was obtained by manual segmentation of CT scan data. An incision along the midline of the sternum model and a suture technique were modelled based on the practice of a local cardiac surgeon as shown in Figure 1a.

Considering that the strain at the cortical bone would not exceed 0.2%, it was possible to create a material model with linear isotropic behaviour. An analysis of the CT scans resulted in an average thickness of cortical bone of 1.38mm. The Young's Moduli of the bone tissues of the sternum were estimated to be 5000MPa and 50MPa for the cortical and cancellous bone respectively[3]. Testing of the stainless steel suture evaluated Young's Modulus to be 193GPa[4].

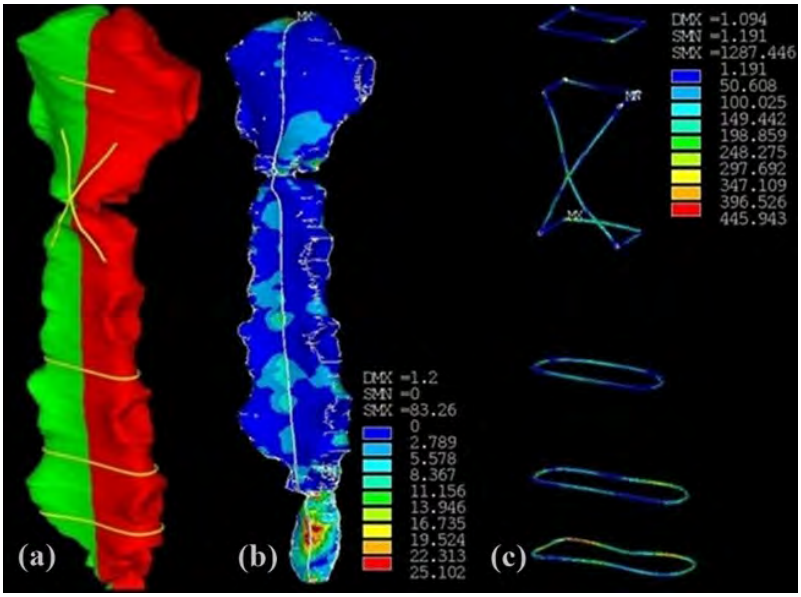
The application of loading and boundary conditions were then assigned. Published results indicate a range for the forces experienced by the sternum starting from 160N to 400N[2] for breathing up to 1650N for coughing[5]. The simulation carried out was based on a mathematical model of the thorax as an ellipsoid pressure vessel with varying chest wall thicknesses. This model provides varying loads at different rib levels increasing from around 250N to 480N, which seem to be reasonable and correspond to *in vitro* experiments[6].

A Finite Element (FE) model was obtained following discretisation and then finalised by setting the contact at the bone-wire interfaces.

Results: The results indicate that the gap between the two halves varies from 0.125 ±6.25e-4mm at the manubrium to 0.904±4.52e-3mm near the xiphoid. This degree of micromotion in response to the dynamic loading promotes the healing

of the wound. The highest von Mises' stress on the sternum cortical bone is observed to be 25.102±0.125MPa at the xiphoid while at the location of the wire sutures, the von Mises' stress on the cortical bone is 11.15±0.056MPa as shown in Figure 1b. Thus all stresses on the cortical bone are below the assumed yield strength of 170MPa[7]. The majority of the uppermost sutures experience a stress below the yield strength of 290MPa[4]. The stress in the sutures is increasing in the caudal direction reaching a von Mises' stress of 446MPa at the bottommost suture as shown in Figure 1c.

Figure:



Caption: Geometrical model of the human sternum with the suture technique; (b) Von Mises' stresses on the two sternal halves, (c) Von Mises' stresses on the sutures

Conclusion: The stress results on the lower region of the sternum are mainly due to the load model and its application at connection of the false ribs. This corresponds to the similar results obtained from a computation prior to incision thus confirming the necessity to provide a correct evaluation of the chest load model. Also the stresses in the suture at the inferior region are much higher than the yield strength of the suture material, which confirms our conclusion mentioned above. The application of this study is to increase the knowledge pool about the bone-wire interface in median sternotomy and to identify the problematic areas on the sternum following such procedure.

POST IMPLANTATION DESIGN OPTIMIZATION OF CORONARY ARTERY STENT

Dimitrios Drougkas [1] Serafim Chatzimoisiadis [1,*]

[1] Optimization Applications, Beta Cae Systems S.A., Thessaloniki, Greece

Introduction and Objectives: The use of stents is an effective and trusted solution for coronary artery stenosis. Their principle of design offers immediate results with minimal recovery time. But how do they stand in terms of reliability after their implantation? Clinical experiments in combination with FEA analysis are performed in order to define the optimal design of coronary stents since it is very important the maintenance of their final shape for the rest of the patient's life, against the complex loading conditions within the arterial walls.

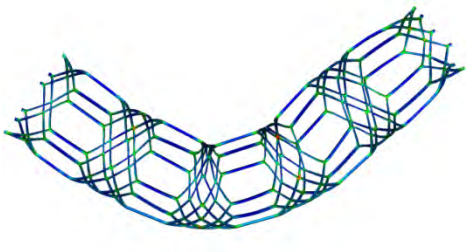
From the engineer's point of view the most crucial loading condition is the cyclic bending of the stent. During which the stent not only has to flex without traumatising the arterial walls, but it has to maintain its effective diameter in order to prevent a restenosis due to mechanical failure.

Methods:

The optimum design and thickness of a flexible metal stent has been determined through an optimization process. Stent shape parameters were defined as morphing parameters in the Pre-Processor and used as design variables for the optimization case. The desired responses were automatically extracted from the results with the aid of the Post - Processor and used as design objectives and constraints. The load cases included crimping (reducing stent diameter), blowing pressure (increasing stent diameter) and also a 3point bending test to ascertain the flexibility of the stent design. The final step was the coupling of the optimizer, the Pre- and Post- Processors and the solver employing the respective build in nodes to set up the optimization process.

Results: The optimum design that was suggested by the optimizer achieved the maximum possible value for the objective variable , the diameter of the stent after the bending test. The design achieved 20.47% larger diameter for the inflation step and 22.15% larger diameter after the bending test in comparison to the initial mode. The optimum design also complied with the defined design objectives providing an overall viable solution to the optimization problem.

Figure:



Conclusion: Concluding, the coronary artery stent design optimization problem was successful in acquiring optimum design using FE mesh morphing techniques, complying with both constraints and achieving optimum results.

FORWARD DYNAMICS SIMULATION OF 3D RUNNING MOTION USING A NEURO-MUSCULO-SKELETAL MODEL

Kazunori Hase [1,*]

[1]Mechanical Engineering, Tokyo Metropolitan University, Hachioji, Tokyo, Japan

Introduction and Objectives: Forward dynamics simulation is important in the research fields of biomechanics, because it autonomously generates human movement such as walking and running in a computer without any motion data collected from actual human, and can complement limitation of the experimental approach. Running includes flying phase, i.e., the entire body floats on the air, which walking does not include, so motor control of running is more difficult than walking. If human running is precisely synthesized by a computer simulation, biomechanical principles of the motion might be clarified computationally and the simulator might become a useful tool for the research field of sports biomechanics. The purpose of this study is to simulate three-dimensional running in humans using a neuro-musculo-skeletal model based on forward dynamics. This study especially focused on synthesizing faster running motion to improve locomotive stability.

Methods: The inertia properties of the whole body were represented by three dimensional 14-rigid-links system with 23 degrees of freedom of the joints. The musculoskeletal model was constructed by 70 muscle models that included mechanical and physiological properties of the muscle. The geometric path of each muscle was expressed by a series of line segments. The interaction between the foot and the ground was modeled as a combination of springs and dampers. The basic motion controller consisted of artificial neural network models including 23 neural oscillators. The neural oscillator mathematically represents the central pattern generator (CPG) in the nervous system. This generates the combined neuronal stimulus for each degree of freedom by receiving a nonspecific stimulus from the higher center of the neuronal system and feedback signal from the sensory feedback system. This feedback system corresponds approximately to the reflexes.

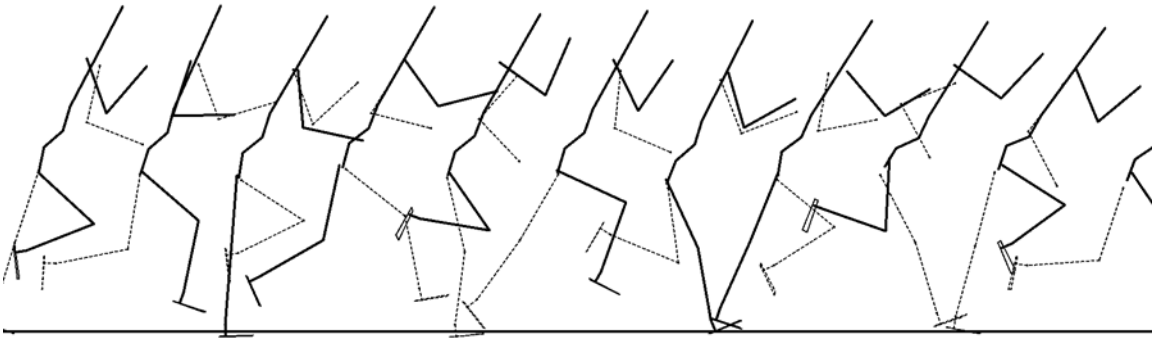
The above-mentioned CPG-based controller was thought to correspond to the lower level function of the central nervous system such as the spinal cord. On the other hand, the cerebellum has been thought to work involuntarily to maintain locomotive balance. We constructed an attracting controller modeled after the involuntary control functions of the brain to maintain locomotive balance. There were two main features of the design of the attracting controller. First, this controller was designed in the reduced-order space composed by the principal components of the joint angles and angular velocities. Second, the attracting controller generated torque signals to maintain regular or desired locomotion patterns only when locomotion was perturbed by some disturbance. The attracting controller was placed in parallel to the CPG-based controller. The CPG-based controller receives somatic sensation signals and generates an oscillatory pattern for the locomotive motion, while the attracting controller receives each joint angle and outputs the signals to return to the regular locomotive trajectory by canceling the disturbance. The signals from the attracting controller and the CPG-based controller are summed for delivery to the peripheral nerve model to stimulate the muscles.

Furthermore, the simulation system included a numerical search method to modify the characteristics of the model according to the purpose of the simulation. The parameters in the neuro-musculo-skeletal model can be changed using genetic algorithms as optimization techniques with evaluative criteria of locomotion and parallel computing techniques.

Running motion was generated by transition from a normal gait using the numerical search. The transition process was divided into two stages. The first stage of the process was the acquisition of the flying phase in which minimizing the period of foot-ground contact was employed as the evaluative criterion. After realizing a running motion with a flying phase, the second stage aimed at maximizing the both of locomotive speed and energy efficiency. Such numerical search process was thought to correspond to learning process of human movement.

Results: In the search process to obtain the desired running motion, solving of the differential equations of the neuro-musculo-skeletal system was conducted until the model walked or ran for only the prescribed six steps. Figure 1 shows synthesized running motion using the proposed model. The running speed was 6.0m/s, the stride length was 2.95 m, and the running cycle period was 0.49 s. The final running pattern agreed closely with that of a human. However, locomotive motion was still unstable and easy to fall down, so it was difficult to realize running speed over 6 m/s.

Figure:



Caption: Fig. 1 Stick pictures of simulated running motion. Each stick picture is traced at 0.1 sec intervals.

Conclusion: In the present study, running motion at a speed of six meters per second was realized using the forward dynamics simulation with a three-dimensional entire-body neuro-musculo-skeletal model.

EFFECT OF ALTERED MUSCLE ACTIVATION PATTERNS ON THE LOADING OF THE ACL DURING JUMP LANDING IN DOWNHILL SKIING

Dieter Heinrich [1,*] Antonie J. van den Bogert [2] Werner Nachbauer [1]

[1]Department of Sport Science, University of Innsbruck, Innsbruck, Austria, [2]Department of Mechanical Engineering, Cleveland State University, Cleveland, United States

Introduction and Objectives: Injury data in alpine skiing highlight that competitive skiers face a high injury risk. In particular, jump landing in downhill skiing has been identified as a common situation leading to ACL injury [1]. During landing maneuvers muscle forces have been shown to significantly contribute to the loading of the ACL either as agonist or as antagonist (e.g., [2]). However, it is unknown how altered activation of individual muscles affects the loading of the ACL taking into account compensatory effects of the other muscles. Therefore, the purpose of the present study was to determine the changes in ACL loading during jump landing in downhill skiing due to altered muscle activation patterns and to determine the muscles with the highest influence.

Methods: A 25 degrees of freedom sagittal plane musculoskeletal model of an alpine skier with two skis was used to study jump landing in downhill skiing [3]. The motion of the skier was actuated by 16 three-element Hill-type muscles, eight for each lower extremity: iliopsoas (ILI), glutei (GLU), hamstrings (HAM), rectus femoris (RF), vasti (VAS), gastrocnemius (GAS), soleus (SOL) and tibialis anterior (TA). The model had 82 state variables $\boldsymbol{x=[q,q',a,L_{CE}]^T}$, where $\boldsymbol{q}$ and $\boldsymbol{q'}$ denote the generalized coordinates and velocities, and $\boldsymbol{a}$ and $\boldsymbol{L_{CE}}$ denote the activations and the contractile element lengths of the muscles. Furthermore, the model had 16 control variables $\boldsymbol{u}$ representing the muscles excitation patterns.

We developed a dynamic optimization framework to study the effect of altered muscle activation patterns on peak ACL loading. Measured kinematic data of a jump landing maneuver served as reference data and were taken from a previous study [4]. In particular, the following performance index was minimized

$J = J_1+J_2$

with

$J_1 = 1/(N_d\ N_f)\ \sum_i\sum_k((q_i(t_k)- q_{i,data}(t_k))/\sigma_i)^2$

and

$J_2 = 1/(N_m\ T)\ {}_0\int^T(\sum_j w_j\ u_j(t)^2)dt$

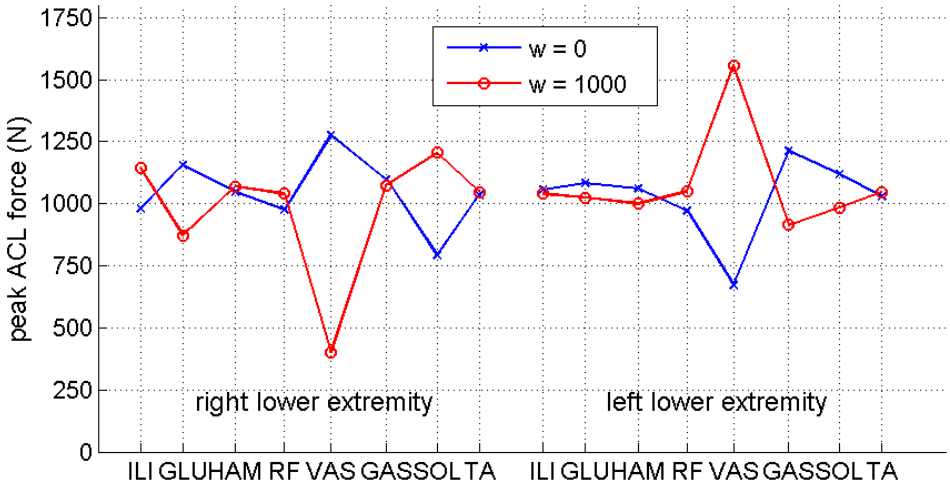
subject to constraints due to system dynamics and unity bounds on $\boldsymbol{u}$. The first term J_1 represents the deviation of the simulation with respect to experimental data. The second term J_2 was used to account for muscle redundancy similar to [5]. The optimal control problem was transformed into a nonlinear programming (NLP) problem [6] and solved using the NLP solver IPOP. Setting the weighting contants w_j to 10 for all muscles resulted in a reasonable weighting between J_1 and J_2. Sagittal knee joint loading was calculated similar as in [3].

The change in ACL loading due to altered muscle innervation was determined by performing two optimizations with different weighting constants w_j for each muscle. A similar approach was used in [7] to study the change in tibiofemoral forces. In the first optimization the weighting constant w_j of a single muscle was set to 0 to encourage activation of the

selected muscle. The weighting constants of the other muscles were not changed. In the second optimization the weighting constant w_j was set to 1000 to penalize activation of the selected muscle.

Results: The measured jump landing maneuver of the downhill skier could be successfully simulated. Peak ACL forces reached 1046 N in the right leg after about 35 ms of initial ground contact. Peak ACL force was sensitive to altered activation of the VAS, SOL, GLU and ILI of the right lower extremity (Figure 1). In particular, encouraging activation of the VAS and GLU as well as penalizing activation of the SOL and ILI increased peak ACL force. On the other hand penalizing activation of the VAS and GLU as well as encouraging activation of the SOL and ILI decreased peak ACL force. Furthermore decreased activation of the VAS in the left lower extremity increased the peak ACL force in the right knee transferring additional load to the right lower extremity. Only a small influence on peak ACL force was observed by altered activation of the HAM. The main reason was compensatory activation of the VAS to track the measured kinematics.

Figure:



Caption: Change in peak ACL force due to altered muscle activation of individual muscles. Setting the weight constant w to 0 and 1000 was used to encourage and penalize the activation of a selected muscle, respectively.

Conclusion: A planar musculoskeletal model of an alpine skier was applied to study the effect of altered muscle activation of individual muscles on peak ACL loading in downhill skiing. While peak ACL force was primary affected by the VAS also muscles not spanning the knee joint affected peak ACL force significantly. Peak ACL force was insensitive to altered activation of the HAM due to compensatory activation of the VAS.

HUMAN CENTERED CAD SYSTEM WITH BIOMECHANICAL ANALYSIS

Younguk Kim [1,*] Yeounghun Kim [1] Sangjun Lee [1] Dooyoung Lee [1] Kunwoo Lee [1]

[1]Mechanical Aerospace Engineering, Seoul National University, Seoul, Korea, Republic Of

Introduction and Objectives: As the market becomes competitive, it is more difficult to sell products with price strategy or development of function. Therefore, human-oriented design system is in the spotlight of manufacturer to satisfy the various demands of consumer. Unfortunately, there is no proper product design system which adequately applies the human factor into the design phase. The conventional design system is time consuming and costly, because a repetitive process is required on producing a prototype to test it on human subjects and then changing the design parameters based on the test results.

According to [1], development costs and time can be reduced by using a digital human model. Moreover, a study by Chaffin et al. [2] implemented a digital human model called 3DSSP or Jack (Siemens, Germany), which is widely used in the industry. In addition, Jung [3] converted a CAD design into an AnyBody Modeling System (AnyBody Technology A/S, Denmark) [4] and executed analysis. However, these studies do not provide an integrated simulation in one system or not specialized in product design.

In order to improve upon the existing studies, this study proposes a method of transplanting a musculoskeletal analysis into a CAD system; therefore, users can evaluate the product model by performing musculoskeletal dynamic analysis during the design process.

Methods: The entire system of this research can be divided into three parts - CAD, motion generator and biomechanical analyzer. In the CAD part, user designs a product and generates a human-product model using the integrated modeling system [5]. For integrated model, human model data are exported from an OpenSim 6 Degree of freedom upper-body model [6].

In the motion generator part, users can calculate the each segment motion with the product's target motion. Also they can achieve the interaction forces between the human and the product. "Independent joint control" method is used by motion generation which considers each joint as an independent object. This method determines each joint control, then it controls the difference with feedback control. [7] The target trajectory x_d is decomposed by the joint control input with a Jacobian relationship. In addition, the actual joint position x can be derived by solving the forward dynamic equation with the joint control input. With this information, we can define the control error for feedback control as follows:

$$\tilde{x}(t)=x_d(t)-x(t) \quad \text{(Eq.1)}$$

The PD control input for error compensation is expressed with gain factor k_p, k_D

$$F(t)=k_p\,\tilde{x}(t)+k_D\,\dot{\tilde{x}}(t) \quad \text{(Eq.2)}$$

According to (Eq.2), each joint control input can be acquired by decomposition of the joint space with a Jacobian J_A

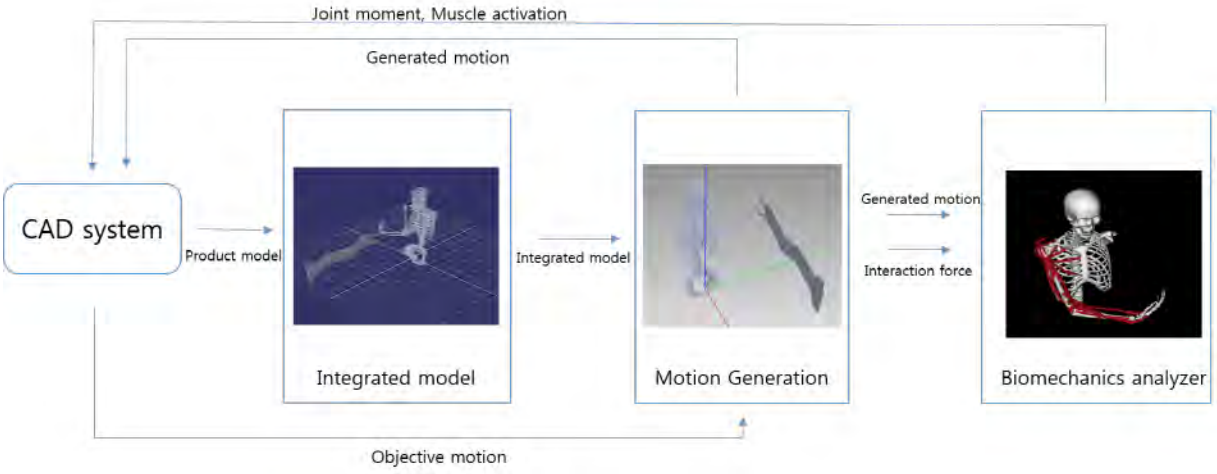
$$u(t)=J_A^T F(t)=J_A^T(k_p\,\tilde{x}(t)+k_D\,\dot{\tilde{x}}(t))=J_A^T(k_p\,\tilde{x}(t)+k_D\,J_A\,\dot{q}(t)) \quad \text{(Eq.3)}$$

The motion is generated by this process with RoboticsLab [8], and the human-product interaction orce is calculated by dynamic equation of motion.

In the biomechanical analyzer part, based on motion and force information, analyzer can calculate each joint torque and muscle activation of the musculoskeletal model. With the OpenSim API, inverse dynamics equation is solved with the motion and interaction-force information. After the interaction force is converted to an external force, it is substituted into the dynamic equation. Joint moment is obtained the by calculating the dynamic equation with force and motion information. Furthermore, we perform optimization to achieve the muscle activation results and metabolic cost.

Results: As shown in (Fig.1), a human-product integrated model is created with product information, which is designed in a CAD system. Integrated model motion and interaction force information are derived from the objective motion and integrated model. In addition, the constructed system performs calculation of inverse dynamics and optimization with the musculoskeletal information. This result is reflected in CAD system. It allows the user to access biomechanical information with one complete system.

Figure:



Caption: Fig 1. System overview

Conclusion: The significance of this research is integration of biomechanics into a CAD system. It allow us to predict the biomechanical effect during the design process without manufacturing. Therefore, it could reduce the time for iterative experiments during the process and possible to suggest the optimal biomechanical design conditions

STUDY OF THE STRESS AND TEMPERATURE OF CORTICAL BONE CUTTING BY MICRO-TEXTURED TOOL

Weihua Fu [1,*] Hongyin Cui [2] Chao Wang [2] Yahui Hu [2]

[1]General Surgery Department, Tianjin Medical University General Hospital, [2]Tianjin Key Laboratory of the Design and Intelligent Control of the Advanced Mechatronical System, Tianjin University of Technology, Tianjin, China

Introduction and Objectives: In bone cutting operations, severe friction exists when the tool is in contact with the workpiece. It causes an increase in bone temperature, and a temperature above 47°C is critical because it causes thermal bone necrosis. In this paper, three kinds of tools with micro textured rake face were fabricated. The purpose of this research is to investigate the improvement of cutting performance in cutting of cortical bone with the micro textured tools and seek the conformable cutting parameters for exertion of the advantages of these tools.

Methods: Numerical models of cortical bone and cutting tool was used to simulate the cutting process by ABAQUS6.11. Parameters of the micro-texture tools and the common tool were selected respectively by single factor analysis. Dry friction tests on the pin-on-disc tribological tester were carried out with these micro textured surfaces and conventional surfaces for comparison. A prediction model of temperature was set up according to a orthogonal experiment design.

Results: The simulated experiment indicated that morphology and geometric parameter differences of the micro-texture cutter caused different temperature changes in the third deformation area, cutting temperature was proportional to spacing and depth of micro-texture, but was inversely proportional to width. Width of micro-texture played a key role in temperature variation . Through the analysis of variance, A prediction model of temperature was proved to be right.

Conclusion: The finite element model and experimental model has the same change trend. The stress and temperature in dry cutting of cortical bone with the micro textured tools was reduced compared with that of the conventional tool. The prediction model of temperature can assist in the selection of favorable cutting conditions for the operations of micro-textured tools.

DEVELOPMENT OF A MUSCULOSKELETAL MODEL FOR THE ANALYSIS AND SIMULATION OF CERVICAL SPINE LOADING DURING RUGBY ACTIVITIES

Dario Cazzola [1,*] Ezio Preatoni [1] Timothy Holsgrove [2] Richie Gill [3] Grant Trewartha [1]

[1]Department for Health, University of Bath, Bath, United Kingdom, [2]School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, United States, [3]Department of Mechanical Engineering, University of Bath, Bath, United Kingdom

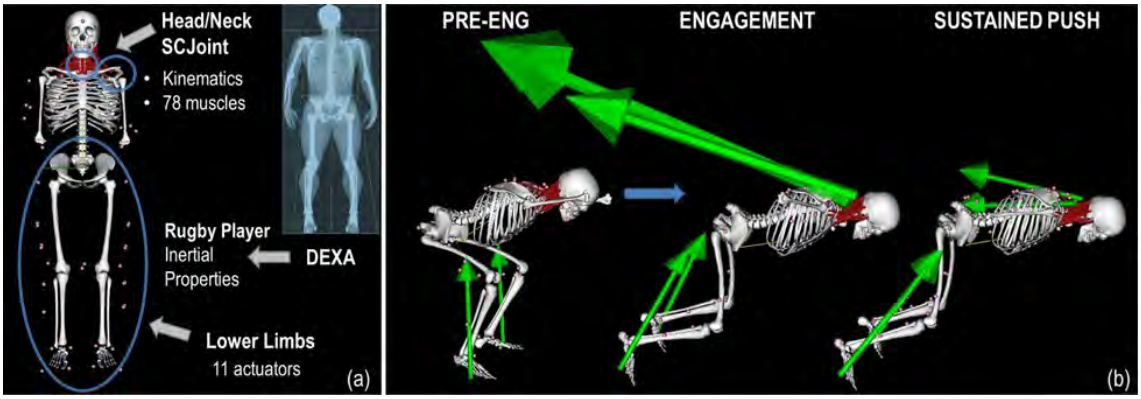
Introduction and Objectives: Musculoskeletal modelling is widely used in biomechanics for the analysis and simulation of human motion, especially to investigate the variables that are not directly measurable through *in-vivo* or *in-vitro* experimental design. An example is the analysis of hazardous situations, such as vehicle crashes or injury scenarios in sports, where direct measures of loading conditions on internal anatomical structures are not feasible or ethical. Musculoskeletal modelling needs to be based on *in-vivo* or cadaveric kinematics and anatomical measurements, to provide reliable analysis and simulation outcomes that are relevant for understanding real-word problems. The aims of this study were to: i) establish a full body OpenSim musculoskeletal model, optimised for simulating rugby activities such as scrummaging and tackling; and, ii) verify the model's suitability during machine scrummaging trials.

Methods: The 'Rugby Model' was developed using OpenSim software (OpenSim 3.2, SimTK) and Notepad++ XML editor. The Rugby Model (Figure 1a) is an upgrade of a refined head/neck OpenSim model [1] embedded into a full body model [2], and consists of 29 rigid anatomical segments divided into lower limbs (femur, tibia, talus, calcaneus and toe), pelvis, trunk (thorax and spine), seven cervical spine vertebrae (C1-C7), scapula, clavicle, humerus and head (skull and jaw). Additionally, 78 upper and lower cervical muscles divided into 19 muscle groups inherited from Vasavada's model [3] were included, along with 17 torque actuators representing lower limb and upper limb muscle actions. Motion between body segments was permitted via 26 joints and 30 joint constraints. Body anatomical segment inertial properties were obtained from a combination of literature [3; 4] and DEXA scan data from a front row rugby player (height 1.84 m, 120.4 kg). DEXA imaging enabled improved mass distribution for the anatomical segments, while the local centre of mass locations and inertia moments were obtained from anthropometric tables [4]. The verification of model suitability for rugby scrummaging analysis was carried out through its application in OpenSim software. The scaling, inverse kinematics and inverse dynamics procedures were performed and the residuals values were compared with reference values in the literature.

Results: A new set of inertia parameters was provided. The Rugby Model includes an existing lower limb model, and comprises two custom scapuloclavicular joint (SCJ) to model the coupled motion of scapula and clavicle with respect to humeral elevation [1]. The model was scaled in OpenSim and a RMS value of 12 mm discrepancy between model marker and marker positions was produced. Inverse kinematics analysis of scrummaging trials showed an RMS value, across all movement phases, of 20 mm. An inverse dynamics analysis was performed and both ground reaction forces and external forces were applied respectively on model lower limb and scapula-clavicular region (Figure 1b). The relation between moment arm and anatomical segment motion, used in the Rugby Model were compared with values in literature [5],

showing that the inclusion of SCJ did not stretch or shorten the cervical spine and upper trunk muscles over their physiological limit. In this way any dynamic analysis including the contribution of muscles to the net joint moment is not negatively affected by non-physiological values of muscles moment arm due to SCJ movements.

Figure:



Caption: Figure 1: (a) Rugby Model includes Head/Neck and scapuloclavicular (SCJ) joints, and inertial parameters from a DEXA scans. (b) Inverse dynamic analysis during scrummaging.

Conclusion: The Rugby Model is the first full body model that provides the foundation for further applications in rugby activities and other sports impacts involving upper body contacts. The Rugby Model includes i) a refined estimation of model inertial properties, and ii) the inclusion of lower limbs in order to allow the simultaneous application of multiple external loads. The model was optimised to provide the kinematics of the cervical spine and scapula-clavicular segments, with coupled joint motion relationships based on cadaveric data. The inclusion of inertial values from DEXA scans enabled inverse dynamics analysis and an improved scaling procedure based on rugby-specific participants. The model will be used to calculate muscle lengths and moment arms, as well as the forces and moments around the cervical spine during rugby activities, such as scrummaging and tackles. The model will be used to investigate cervical spine injury mechanisms during rugby scrummaging. Further modelling developments will integrate MRI data into the construction of subject-specific models.

DIFFERENCES IN MORPHOLOGICAL PARAMETERS AND PATTERNS OF INTERFERENCE AT THE HIP IN NORMAL AND FAI PATIENTS

Ramya Namani [1,*] Charanya Chandrasekaran [2] Javad Parvizi [3] Sorin Siegler [1]

[1]Mechanical Engineering and Mechanics, [2]Biomedical Engineering, Drexel University, [3]Rothman Institute, Thomas Jefferson University, Philadelphia, United States

Introduction and Objectives: Femoro-Acetabular Impingement (FAI) is a clinical condition characterized by limited range of motion due to early abnormal bone-to-bone interference and is often associated with labrum and cartilage damage leading to osteoarthritis [1]. Previous studies [2, 3] suggest that the early interference at the hip joint and FAI are due to abnormal morphology of the bones. The purpose of this study is to further test this assumption by comparing the morphology and the patterns of bone interference during motion of the hip between healthy subjects and patients diagnosed with FAI.

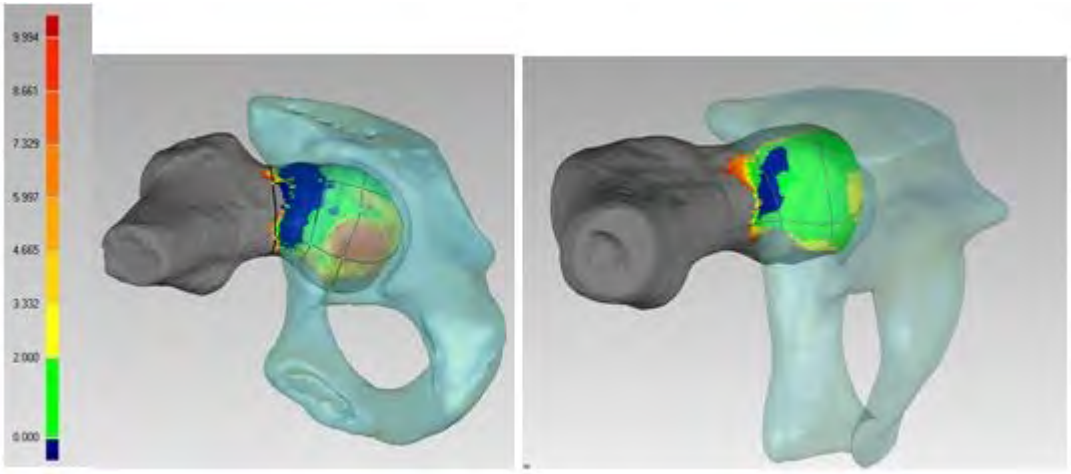
Methods: Computerized Tomography (CT) images (resolution: 0.8mm*0.8mm*2mm) from seven healthy, non-symptomatic subjects and ten age-matched FAI patients were acquired. The CT images were processed through segmentation in ANALYZE™ software to produce 3D numerical models of the femur and the acetabulum. Twenty seven morphological parameters representing common clinical parameters for the acetabulum, femur, and acetabulum-femur relations were measured from the 3D bone models. These morphological parameters were compared between the healthy and FAI subjects using statistical analysis based on t-test. For each subject, a 3D hip model was produced in which the assumed center of rotation of the hip was taken as the average location between the femoral head center and acetabular center. Motion of the hip model was produced and analyzed in a software environment ADAMS™. For the simulation, boundary conditions consisted of a fixed acetabulum and a free femur to which moments were applied in various anatomical directions to simulate clinical tests of FAI [1] consisting of Flexion (100^0) followed by adduction followed by internal rotation. An Interference Detection Algorithm (RAPID™) was used to detect when and where during the simulated motion contact between the proximal end of the femur and the acetabulum occurred. In order to compare the patterns of interference the femoral head was divided into 18 zones. 6 zones starting from anterior-inferior to anterior-superior and each further divided into medial, superior and lateral regions to produce the 18 zones. The interference patterns were calculated using distance maps and were compared within the subjects and between the normal and FAI subjects at each simulated position.

Results: The following parameters were found to be significant different between normal and FAI subjects: Acetabular diameter (FAI: 52.52±3.87mm, normal: 45.93±3.5mm), acetabular width (FAI: 18.84±4.3mm, normal: 14.54±2.22mm), peak-edge distance (FAI: 18.84±4.3mm, normal: 14.54±2.22mm), femoral neck length (FAI: 105.50±6.00mm, normal: 28.49±3.45mm), femoral head diameter (FAI: 48.73±4.2mm, normal: 3.055±1.15mm), alpha angle (FAI: 65.60^o±14.68^o, normal: 39.98^o±18.70^o), two tear drop distance (FAI: 112.59±7.16mm, normal: 128±4.522mm).

The FAI subjects had interference at the anterior-inferior region of femoral head-neck junction starting at 100^o flexion with 20^o adduction and going through 100^o flexion combined with 20^o adduction and 40^o internal rotation. In contrast, for the

normal subjects, 3 subjects did not have interference in any of the simulated positions and 4 subjects have interference only at the extremes of motion such at 100° flexion with 20° adduction combined with 30° at the anterior-inferior region of femoral head-neck junction.

Figure:



Caption: Interference in FAI hip (left) and normal hip (right) at the simulated position of 100 degrees flexion combined with 20 degrees adduction and 30 degrees internal rotation. Blue region on FAI joint shows the region of contact.

Conclusion: Some common morphological parameters were found to differ significantly between normal and FAI subjects. The early interference observed in the FAI subjects support the earlier studies documenting restricted range of motion in FAI. The results also suggest, that several morphological parameters may be related to FAI and these should be considered when evaluating and planning surgery.

CONTROL SIMULATION OF 5D AND CYLINDRICAL GRASPING BASED ON PCA

Javier Andres [1,*] Marta C. Mora [1] Joaquin L. Sancho [1]

[1] Mechanical Engineering, Universidad Jaume I, Castelló de la Plana, Spain

Introduction and Objectives:

Human hand grasping is a very complex process that has been studied for years under different perspectives in the field of hand biomechanics [1-3]. Its characterization is the key for hand prosthetic control. In a previous work [4] the use of kinematic reduction as a rational generalized method for studying grasping postures was proposed. In particular, Principal Component Analysis (PCA) was applied to reduce the hand kinematics while grasping cylinders, and to study the effect of the cylinder diameter and weight, as well as that of the subject, on the grasping posture for cylindrical (C) and 5-digit pinch (5dP) grasps. The PCA showed that the hand kinematics is actually low-dimensional for grasping tasks, and can be efficiently described by a small number of Reduced Kinematic Variables (5 RKVs) for C and 5dP grasps with all fingers.

In [5, 6] we proposed a self-contained hand biomechanical model for grasping simulation. Here, we extend the previous work and tackle grasp posture planning with Artificial Neural Networks (ANN).

The present research initially reviews the previously cited RKVs by means of an ANN. Then, electromyography prosthetic control is simulated by means of a real time modulation of those RKVs as inputs of an ANN. The outputs are the hand joint angles during the grasping trajectory. Graphical validation is done in a hand model with Opensim® software.

Human hand grasping is a very complex process that has been studied for years [1-3]. Its characterization is the key for hand prosthetic control. In a previous work [4] the use of kinematic reduction as a rational generalized method for studying grasping postures was proposed. In particular, Principal Component Analysis (PCA) was applied to reduce the hand kinematics while grasping cylinders for cylindrical (C) and 5-digit pinch (5dP) grasps. The PCA showed that the hand kinematics is actually low-dimensional, and can be described by 5 Reduced Kinematic Variables (RKVs) for C and 5dP grasps.

In [5, 6] we proposed a self-contained hand biomechanical model. Here, we extend the previous work and tackle grasp posture planning with Artificial Neural Networks (ANN).

The present research initially reviews the RKV concept by means of an ANN. Then, electromyography prosthetic control is simulated by means of modulation of those RKVs. The outputs are the hand joint angles during the grasping trajectory. Graphical validation is done with Opensim®.

Methods: In the kinematic model in [5] the human hand is considered to be composed of 5 open chains connected to the carpus through different joints (25 DOFs).

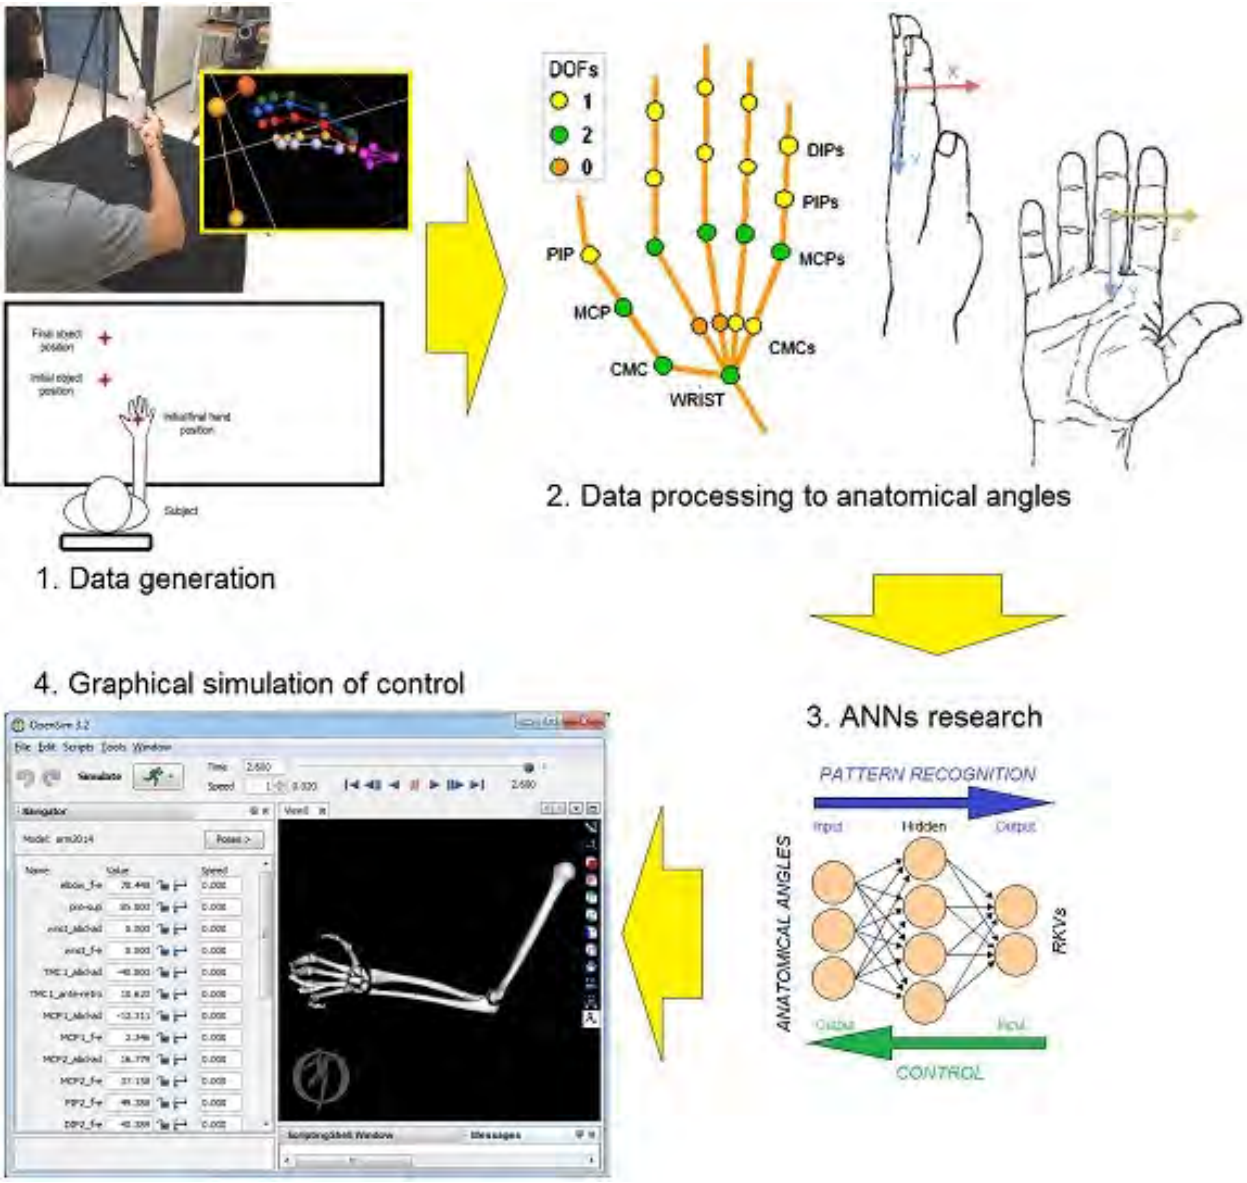
Grasping experiments were performed with 8 right-handed subjects and 4 cylinders of various diameters. Subjects carried out transportation tasks with C and 5dP grasps. Each test was repeated 3 times and the 3D positions of 32 markers were recorded using a motion capture system (infrared Vicon© system). The evolution of 25 joint angles describing the hand grasping posture was computed from the markers' positions over time, using the method described in [7].

Pattern recognition and control are implemented by using a 2-layer feed-forward ANN with 100 neurons in the hidden layer, as in [6]. A training set is established by identifying and associating min/max numerical intensity values of the postures associated to each RKV described in [4]. The resulting ANN manages to identify the same patterns and their intensities in new sets. Thus, a new ANN is trained to control the evolution in hand posture, by varying the intensity modulation of the RKVs value.

Results: ANNs are a powerful method that allows modeling cumbersome dependencies. They are recognized as the most effective and appropriate artificial intelligence technology for pattern classification and control.

After the appropriate ANN has analyzed the dataset (network training), it can make predictions based on hidden dependencies.

Figure:



Caption: Flow process from data acquisition to ANN control simulation

Conclusion: The proposed studies are of high interest for the control of prostheses by a few electromyography signals in real time.

PO-0206

PROPOSAL OF A THREE-DIMENSIONAL TENNIS FOREHAND MODEL

Takuya Otsu [1,*] Norihisa Fujii [2]

[1]Health and Sport Sciences, University of Tsukuba Graduate School, [2]Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan

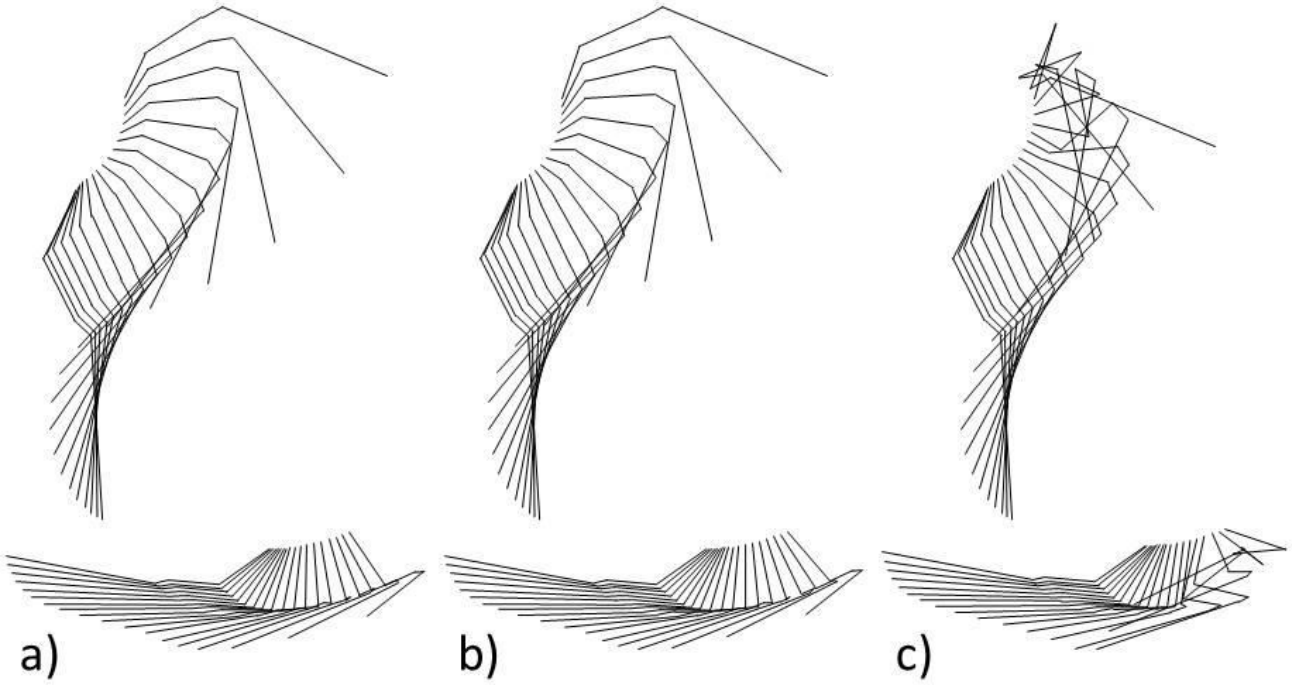
Introduction and Objectives: The tennis forehand groundstroke is one of the most important techniques in rallies. Elite players dictate games by using the powerful and precise forehand (Landlinger et al., 2010). In the real world, it is impossible to adapt various factors for various objectives and to induce ideal results simultaneously and instantaneously. Thus, in order to clarify the optimal forehand, an optimization technique including forehand simulations is essential. In the optimization studies, the simulations which meet some objectives reasonably were presented in ball pitching (Fujii and Hubbard, 2002) and high jump (Wilson et al., 2007), and such methods have been proven to be very useful. But very few researches on the optimization of the forehand have been reported. Moreover virtually no investigation on the forehand simulation model has been implemented. The objectives of this study were to formulate the forehand simulation model for the optimization and to evaluate the model.

Methods: One Japanese varsity-level tennis player participated in this study. The forehand motion was captured with twelve high-speed video cameras (500 Hz; VICON). The 3-D coordinates of the body land marks were collected to calculate the joint torques of an upper extremity. The racket-side arm was modeled by four segments: upper arm, forearm, hand, and racket. (1) The equations of motion, (2) the kinematic constraint equations, (3) the equations representing the degree of freedom for each joint (Fujii and Hubbard, 2002) were formulated as a matrix form Ax = b, where A is a coefficient matrix, x is a column vector comprising the variable to be calculated, and b is a column vector comprising the known values (Casius et al., 2004). The equations were solved with the Runge-Kutta method. To calculate a segment's orientation from its angular velocity, its angular acceleration and velocity were converted into Eulerian angles before integrations. The control variables of the model were time sequences of a shoulder horizontal adduction/abduction torque, adduction/abduction torque, and internal/external rotation torque; elbow flexion/extension torque; hand and racket angular accelerations. The control variables for hand and racket angular accelerations enabled the simulated motion to be proper for forehand. The output variables were motions of upper arm and forearm, elbow varus/valgus torque and pronation/supination torque, wrist flexion/extension torque, radial/ulnar flexion torque, and internal/external rotation torque. In order to evaluate this model, a matching simulation, which is the simulated forehand motion with the measured torques and angular accelerations, was compared with the captured motion. The simulation was carried out for the forward swing phase which was the phase from a completion of backswing to an impact. Then simulations with different conditions were implemented in order to check the sensitivity of the control variables. In condition 1, the peak timing of shoulder horizontal adduction torque was hastened by 5% of forward swing phase time. In condition 2, the peak timing of shoulder internal rotation torque was hastened by 5% of forward swing phase time.

Results: RMSs between the matching simulation and the captured motion were 0.12 rad/s^2 for angular accelerations and 0.003 Nm for output torques. Good consistency was observed between these two motions. It is considered that this model

represents the real forehand properly. Figure shows the stick figures of simulations in different conditions. The change in the shoulder internal rotation torque largely affected the motion. Table indicates the impact parameters, maximums and minimums of the constraint torques. In condition 2, it is observed that the much larger torque was needed to maintain the orientations of hand and racket.

Figure:



Caption: Stick figures of the matching simulation and the simulations with different conditions. Upward = bird's-eye view. Downward = lateral view. (a)Matching simulation; (b)Condition 1: The peak timing of the shoulder horizontal adduction torque was hastened.; (c)Condition 2: The peak timing of the shoulder Internal rotation torque was hastened.

Conclusion: The 3-D forehand simulation model was formulated for the steady integration and easy estimation of a success shot. The simulation model in this study can reduce the computational cost because of its fewer control variables.

Table:

Simulation	Racket face speed (m/s)	Swing direction difference (degrees)	Elbow varus(+)/ valgus(-) torque	(N·m)	Wrist internal(+)/ external(-) rotation torque	(N·m)
			Maximum	Minimum	Maximum	Minimum
Match	32.5	0.0	95.4	-125.4	17.6	0.7
Condition1	32.4	1.2	94.9	-124.0	19.3	0.7

PO-0207

THE SENSITIVITY OF OCCUPANT INJURY OUTCOME TO ERRORS IN DELTA-V PREDICTION

Rebecca Pride [1,*] Donald Giddings [1] David Richens [2] Donal McNally [1]

[1]The University of Nottingham, [2]Cardiothoracic surgery, Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom

Introduction and Objectives: The aim of this study is to identify the variance in predicted occupant injury due to expected errors in the calculated delta-V (ΔV). The ΔV value is a descriptor of vehicle motion during a collision and its accuracy is dependent on the accuracy of input parameters used in its calculations. The Abbreviated Injury Scale (AIS), a non-linear severity scoring system, is used to describe injury severity and can be predicted by use of injury criteria.

Methods: In all selected collisions the occupant sustained a fatal aortic rupture allowing them to be broadly comparable in terms of known injury outcome and as there are two well documented thoracic injury criteria, Viscous Criterion (VC) and Combined Thoracic Index. The nature of each collision was such that the ΔV calculation was valid. The ΔV value was either obtained from the police collision reports or calculated using standard protocols. A confidence interval for the value of ΔV was determined using the sensitivity values of ΔV to its input parameters. MADYMO® software was used for the simulations with a triangular crash pulse to represent a typical collision. The injury criteria used to predict AIS injury severity included the Head Injury Criterion (HIC_{15}), Neck Injury Criterion (Nij) and the Combined Thoracic Index (CTI). The Maximum Abbreviated Injury Score (MAIS) is the highest assigned AIS level across all body regions.

Results: The variance of ΔV had little effect on the predicted AIS score for each of the regions documented; 87% of low and the high run predictions were within 1 AIS level to the mid run (Table 1). The occupant in one simulation sustained a 3 point increase in thoracic AIS level in the high ΔV run due to impact with the steering wheel, this indicated that the two lower ΔV were not representative of the actual collision due to the low ΔV values. ΔV variance had little influence on the location of the most serious injury, and the locations with AIS > 3. Thoracic and head injuries with AIS > 3 were predicted over a large range of ΔV values whereas this only was seen in high ΔV in the neck region. The results show valid representation of collisions with a ΔV > 8ms^{-1} but indicated that collisions with lower values require more precise measurement and calculation.

Conclusion: The expected errors in the calculation of ΔV did not result in significant variance of predicted occupant AIS; this indicates that the data collection methods for the calculation of ΔV are of sufficient accuracy to successfully predict occupant injury through simulation.

Table:

	ΔV	AIS value					MAIS	Location of MAIS	Areas of AIS > 3
	(ms^{-1})	Head	Neck	Thorax	Femur	Tibia			
Peugeot	16.1	3	5	4	3	3	5	Neck	Neck, Thorax
	19.23	5	5	5	3	3	5	Head	Head, Neck, Thorax
	22.3	5	5	6	3	3	6	Thorax	Head, Neck, Thorax

FINITE ELEMENT SIMULATION OF DRILLING FORCE IN CORTICAL BONE WITH EXPERIMENTAL VALIDATION

Yahui Hu [1,*] Jianbo Sun [1] Qingyun Zhang [1] Weihua Fu [2]

[1]Tianjin Key Laboratory of the Design and Intelligent Control of the Advanced Mechatronical System, Tianjin University of Technology, [2]General surgery Department, Tianjin Medical University General Hospital, Tianjin, China

Introduction and Objectives: Bone drilling causes an increase in bone temperature, and a temperature above 47°C is critical because it causes thermal bone necrosis. Prediction and control of drilling force is critical to the success of operations involving bone drilling. This paper studied the changes of drilling force in the process of drilling cortical bone, and a prediction model of drilling parameters about drilling force was built.

Methods: A numeric approach was adopted. The three-dimensional finite element model with Abaqus6.11 was used to simulate bone force. A prediction model was set up according to a orthogonal experiment design. By comparing the finite element model with the experimental results, the influence of the drilling parameters on drilling force was gotten, and further the reliability of the finite element model and the prediction model of drilling force were verified.

Results: Results of analysis indicated that the bit diameter affected drilling force most, feed rate was the second, and drilling speed was the smallest. The increase in drill diameter and feed rate caused increase in drilling force, the increase in drilling speed caused decrease in the drilling force. The predicted results were also proven to be in accordance with the experimental results, but it was always greater than experimental. There were some deviations which was within 15% between finite element model and experimental model.

Conclusion: The drilling force of finite element model and experimental model has the same change trend. The FE model can predict the drilling force with reasonable accuracy. The prediction model of drilling force can assist in the selection of favorable drilling conditions and drill-bit geometries for bone-drilling operations.

MRI-BASED PARALLEL MECHANISMS TO MODEL SUBJECT-SPECIFIC JOINT KINEMATICS

Simao Brito Da Luz [1,*] Luca Modenese [1] Nicola Sancisi [2] Peter Mills [1] Belinda Beck [1] Thor Besier [3] David Lloyd [1]

[1]Center for Musculoskeletal Research, Griffith University, Gold Coast, Australia, [2]DIN, University of Bologna, Bologna, Italy, [3]ABI, University of Auckland, Auckland, New Zealand

Introduction and Objectives: Subject-specific musculoskeletal (MSK) computer models can estimate muscle and joint articular forces, enabling the identification of mechanical factors causing joint injury or disease. MSK models include models of skeletal anatomy and joint kinematics that can be created in OpenSim [1]. These models are generic and undergo simple linear scaling to a subject using markers from motion analysis. However, generic scaled MSK models produce less accurate estimates of measured knee articular forces compared to those that are subject-specific [2]. Thus, methods are needed to readily create subject-specific models.

Passive tibiofemoral (TFJ), patellofemoral (PFJ) and talocrural (TAJ) kinematics measured in cadavers are well predicted using 3D parallel mechanisms [3,4]. These models integrate the cadaver's measured bone, ligament and tendon geometries to constrain the joints' degrees of freedom (DOFs). Using TFJ flexion angle as input, TFJ and PFJ models estimate the tibia's and patella's remaining Flex-Extension (FE), Abd-Adduction (AA), Int-External (IE) rotations and Ant-Posterior (AP), Prox-Distal (PD) and Med-Lateral (ML) translations. Similarly, TAJ models use talus flexion angle to estimate kinematics from the other TAJ DOFs. However, these models have only been used in cadavers where the kinematics were accurately measured and used to tune the models geometrical parameters.

We aimed to use MRI images of *in vivo* lower limb bones, cartilages and ligaments to create models' geometrical parameters. Using previously described mechanisms [3,4] we estimated subject-specific kinematics for use in OpenSim. However, without measured kinematics to tune the model, we created specialized algorithms to solve the mechanisms and then compared the results with those from cadaveric studies.

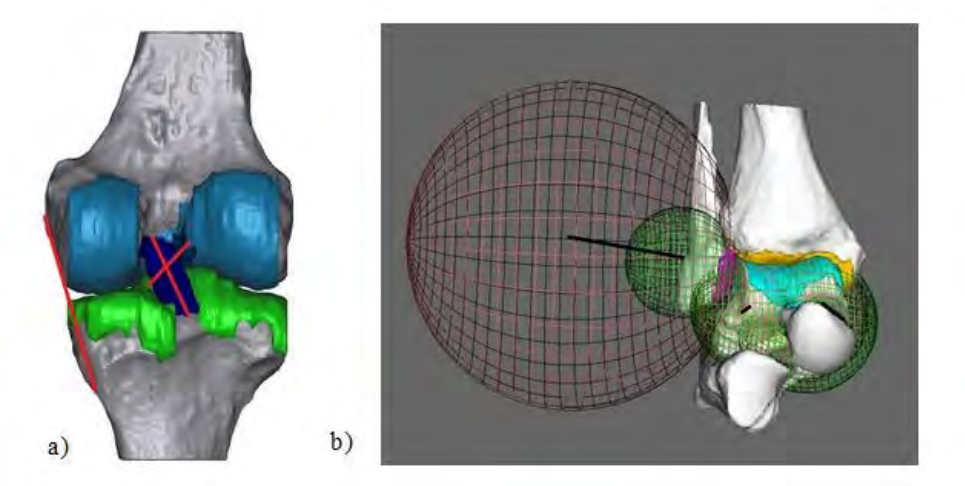
Methods: TFJ, PFJ and TAJ models were modified from [3,4] so that parameters could be determined from MRI. Participants (n=14) were scanned in a 3T MRI scanner with axial slices of the complete limb and sagittal slices of the hip, knee and ankle. Segmentation, alignment and smoothing were performed generating 3D surfaces (Fig.1) and bones' coordinate frames according to ISB standards. Spheres were fitted to the articular surfaces of the femur, tibia, fibula and talus. Two spheres were also fitted to the femoral trochlea with their centers defining the PFJ hinge axis. Ligament and tendon attachment points were initially represented by the centroid of each attachment surface.

For TFJ flexion angles from 0° to 90° the other TFJ and PFJ DOFs were determined using the mechanisms, by minimizing the changes in 1) distance between the spheres' centers, and 2) ligament lengths. TAJ model was a similar mechanism, using FE angles from -25° to 15°. For each subject, model parameters were tuned via simulated annealing including constraints to 1) avoid mechanism singularities, 2) match cadaveric kinematics patterns, and 3) minimize the difference between tuned and initial measured parameters. Our algorithm also ensured the tuned 1) ligaments' attachments remained within their bone attachment areas, and 2) sphere centers and radii well matched the cartilage surface point clouds.

Pearsons' correlations were calculated between the mechanisms derived kinematics and those from cadaveric studies. Sensitivity analysis was performed to verify how robust results were to the tuned parameters.

Results: Derived kinematics had no singularities and were very similar to the cadaveric data (Table.1). Differences in participant's anatomy compared to cadavers may explain some of low correlations. Nevertheless, good overall correlations indicate that models can be used to reproduce subject-specific kinematics. Sensitivity analysis suggested that TFJ, PFJ and TAJ models' were more dependent respectively on tibia's MCL insertion, tibia's patella tendon insertion and tibia's distal-lateral sphere center.

Figure:



Caption: Figure 1-a) TFJ surfaces with ligament links, b) Spheres fitted to TAJ surfaces

Conclusion: TFJ, PFJ and TAJ kinematics can be estimated using 3D mechanisms with parameters obtained from MRI. These can be used in OpenSim and MSK models and may improve estimates of muscle and joint contact forces.

Table:

PROTECTION OF ANKLE BRACE ON ANKLE SPRAIN DURING PARACHUTE LANDING

Junchao Guo [1,*] Lizhen Wang [1] yubo fan** [1]

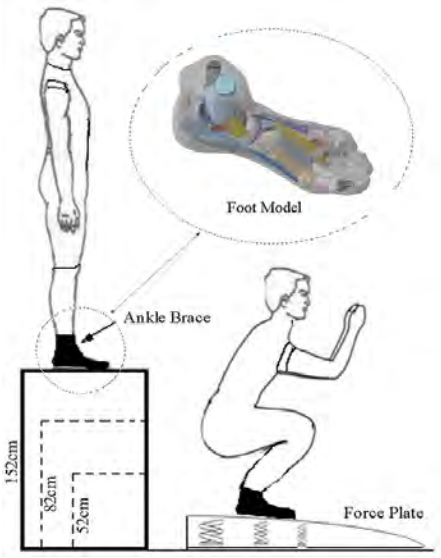
[1]Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, School of Biological Science and Medical Engineering, Beihang University, Beijing, China

Introduction and Objectives: Ankle injuries were the most common injuries in running and jumping. Ligament injuries of ankle in US army paratroopers were reported annually [1]. 74% of all ankle injuries were ankle ligament sprains, and 85% of ligament sprains were caused by an inversion trauma. Ankle injuries accounted for 30 to 60% of all parachuting injuries. This study was aim to investigate the protection of ankle brace for lateral ankle joint during parachute landing.

Methods: A group of 16 adult male participated in this study. They had no acute lower extremity injury and previous ankle injury or surgery. Average weight was 71.3Kg at 25years old. Subjects with ankle brace stood the predefined platform, and jumped from the different height of platform (152cm, 82cm and 52cm) [2] on force plate (FP4060-08-100, Bertec, Inc, USA) (Fig.1). The data of ground reaction force in landing experiments was recorded at 1000Hz sampling frequency. To establish the outer ankle brace profile, point cloud was obtained by 3D Scanner (Tianyuan, Inc, China). Impact time and plantar pressure were measured during parachute landing on 20°slope. Then a finite element model of the complex foot structures including bones, cartilage, ligaments, fascias, soft tissue and skin was developed to contrast the effect of no ankle brace and outer ankle brace on lateral foot ankle (Fig.1).

Results: Peak plantar pressure of 11.12MPa in F-Scan measurement was predicted at the lateral forefoot region when volunteer loaded on 20°slope. This was consistent with the results in FE prediction. Plantar pressure after the outer ankle brace was redistributed in medial and lateral of forefoot and heel region. To some extent, peak plantar pressure was decreased. Whilst the strain of calcaneofibular ligament and anterior talofibular ligament reduced 32.6% and 32%, respectively.

Figure:



Caption: Simulation landing on force plate from the different height of platform and foot model

Conclusion: Protection of ankle brace could be important to protect the lateral ankle joint during parachute landing on slope. In particular reduced the risk of lateral ankle ligaments sprain.

STREAMING FLOW FROM MICROBUBBLES ACTIVATED BY ULTRASOUND IN A BLOOD VESSEL MODEL

Kyehan Rhee [1,*] Eun Jin Cho [1] Gon Khang [2]

[1]Mechanical Engineering, Myongji University, [2]Biomedical Engineering, Kyung Hee University, Yongin, Korea, Republic Of

Introduction and Objectives: Recently, ultrasound contrast agents (UCAs) have been applied to therapeutic purpose in order to increase the specificity and efficiency of drug delivery. Ultrasound enhances drug delivery incorporating UCAs can induce temporary increase of tissue and cellular membrane permeability, which is achieved by the pressure and stress fields caused by cavitation of microbubbles. Transport of UCAs towards vessel walls is desirable because therapeutic compounds attached to UCA shells can binds more efficiently to the vessel well as well as near wall bubbles generate strong wall stress field. Most studies on bubble oscillations, translation and streaming induced by oscillating bubbles were limited to a single bubble, and bubble cluster formation and streaming from microbubble foam have been studied less. The formation of bubble clusters and streaming from them may be of interest in therapeutic application of UCAs. In this study, we analyzed the streaming flow induced by bubble cluster motion and oscillation, and observed UCA cluster formation and translation by ultrasound sonication.

Methods: An elastic tube with the inside diameter of 3 mm was manufactured from a silicone resin (Sylgard 184, Dow Corning, NH). The silicon tube was inserted into the polycarbonate container (150x120x35 mm^3), and filled with distilled water for ultrasound transmission. A 15.5 mm diameter hole was drilled for ultrasound probe (1.0 MHz, i3-0108-P, Panametrics-NDT, Waltham, MA) insertion. Acoustic pressure was measured using a calibrated 0.2 mm PVDF needle hydrophone (Precision Acoustics Ltd, Dorchester, UK) at the tube surface. The UCA Sonovue® (Bracco, Milano, Italy) was mixed in 5ml of deionized water, resulting in $2x10^8$ mirobubbles per milliliter solution. Fluorescent particles with a diameter of 7 μm were also mixed with the solution for flow visualization. The UCA and fluorescent particle mixture in distilled water was infused to the silicon tube using a syringe pump (KDS Legato100, KD Scientific, MA). The test section was place on top of a microscope (BX51, OLYMPUS Co., Japan) equipped with a high-speed camera (MIRO EX4, Vision Research Inc., NJ). Particle image velocimetry (PIV) was used to measure the streaming flow fields. In order to obtain the particle images, the fluorescent images of particles were captured at a frame rate of 1,000 fps. They were processed with commercial PIV software (Insight-3G, TSI Inc., MN) for velocity field measurement. The field of view was 4.5 mm×3.5 mm, and the interrogation window size was 16×16 pixels with a 50% window overlap. Because time interval of two consecutive images was much longer than the period of incident pressure wave, measured velocity showed mean nature of flow streaming for 1 ms.

Results: The ultrasound probe was activated by a continuous sinusoidal voltage signal. The signal was amplified up to 50 volts, and incident pressure amplitude at the tube surface was 500 kPa. The UCAs were unevenly distributed over the test section before sonication. When 1 MHz ultrasound of sonication started, microbubbles attracted and repelled by secondary radiation forces and formed clusters near the pressure nodes within 100 ms. These clusters coalesced to form microforms, and translated in the direction of the ultrasound field owing to primary radiation forces. The resulting microfoams further moved to the tube wall, and remained in the stable position afterwards. Further movement of

microforms was not observed, because radiant and drag forces on the microforms were balanced. This observation agreed with the UCA cluster formation in a capillary with diameter of 200 micrometers. Movement of micro clusters and microform induced the vortical flow fields, and the center of clockwise vortex moved to the lower region of an image frame. Streaming velocity was order of 10 mm/s, and the maximum velocity of 15 mm/s was also observed at some locations. Once microforms stayed in a stable position, coherent vortical streaming flow over the tube was not observed. Local streaming from the oscillating bubbles or small clusters was detected, and local streaming velocity was less than 10 mm/s.

Conclusion: In this study, UCA coalescence, cluster formation and translation by ultrasound sonication was observed, and flow streaming induced by micro bubbles and foams were measured. Microbubbles formed clusters within a few hundred microseconds and translated to the wall by primary radiation force of 500 kPa acoustic pressure, and remained in the position where primary radiant force balanced with the drag force. Bubble cluster motion in a tube induced vortical flow with the streaming velocity of about 10 mm/s. Once the bubble clusters located in a stable position, this vortical streaming was disappeared and local streaming from small oscillating bubbles was observed. Streaming velocity from stably oscillating bubbles was less than 10 mm/s.

A DUAL SLICE-TO-VOLUME REGISTRATION METHOD FOR MEASURING THREE-DIMENSIONAL KNEE KINEMATICS IN VIVO USING REAL-TIME MRI

Cheng-Chung Lin [1] Tung-Wu Lu [1 2,*] Chao-Yu Hsu [3] Ting-Fang Shih [3]

[1]Institute of Biomedical Engineering, National Taiwan University, [2]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, [3]Department of Radiology, College of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Accurate knowledge of the three-dimensional (3D) kinematics of the tibiofemoral and patellofemoral joints *in vivo* are essential for a better understanding of the function of the joints and for relevant clinical applications. However, radiation free methods for such information are limited. Recently, our group has developed a method based on the registration of 3D MRI volume and single-slice real-time MR images at a high spatiotemporal resolution obtained by a novel real-time MRI technique [1] (WIP 610, Siemens) to measure 3D kinematics of the femur and tibia [2]. But, this approach did not enable accurate measurement of the 3D kinematics of the patella. To bridge the gap, the current study aimed to develop a new approach based on the novel real-time MRI with dual slice scheme. This new method was evaluated for the accuracies in measuring 3D poses of the tibiofemoral and patellofemoral joint during knee flexion/extension.

Methods: Four healthy adults (age: 23 ± 0.0 years) participated in the current study with informed written consent as approved by the Institutional Research Board. The subject was examined at a prone position in a 3-Tesla MRI system (Verio, Siemens, Erlangen, Germany) with the thigh and shank fixed to a purpose-built jig, allowing passive knee flexion/extension as the thigh remained stationary. A neck matrix coil was applied for imaging the knee joint.

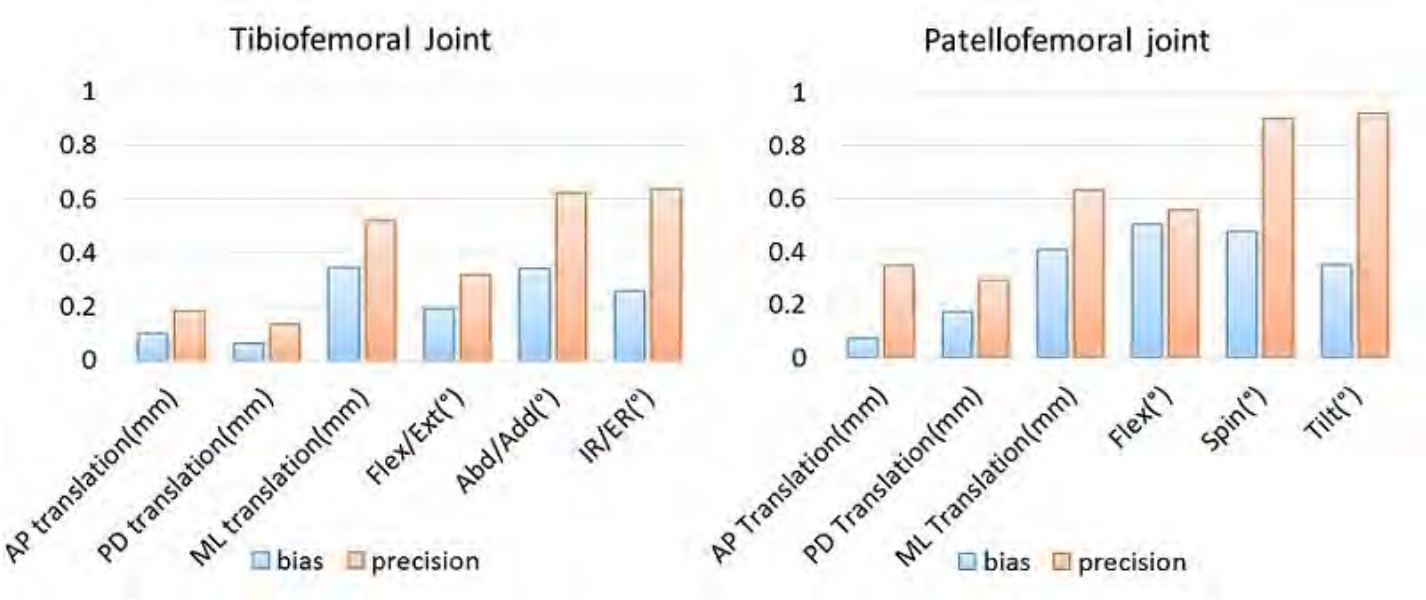
Static multi-slice 3D images and dual slice real-time images of the knee joint were acquired separately at five static positions using MRI. The parameters of the MRI sequences followed our previous study [2]. The positions of dual slice images were adjusted to intersect with both the femoral and tibial shafts with an inter-slice distance of approximately 22 mm. Real-time images of the knee were then acquired at each of the static positions with an effective temporal resolution of 3 frames/s, giving 46 × 2 images per position.

The MR-derived models of the femur, tibia and patella were segmented from the 3D MRI data set. The proposed dual slice-to-volume registration method (DSVR) was based on the registration of a 3D volumetric bone model to the dual slice real-time images. That is, the six degrees-of-freedom of an individual bone at each instance were determined when two reformed images interpolated from the bone model [2] best matched the two real-time MRI slices according to a gradient difference criterion.

The accuracy of the proposed DSVR was evaluated using the data from the static trials. The gold standard poses of the tibiofemoral and patellofemoral joints were obtained from the static 3D image data set. The measurement errors were determined as the differences between the gold standard and the DSVR-determined poses. The accuracy of the method was expressed in terms of the bias and precision over all trials and all subjects.

Results: The bias and precision of the DSVR-determined tibiofemoral joint poses were all within 0.51 mm and 0.64 degree for translations and rotations respectively (Fig. 1). The performance of the method for the patellofemoral joint poses were slightly worse, with the bias and precision within 0.64 mm and 0.92 degree for translations and rotations respectively (Fig. 1). Compared with previous fluoroscopy-based methods [3], the DSVR method has much better medial-lateral translational precision while maintaining comparable accuracies in the rotational components. When compared with our previous single slice-to-volume registration method [2], current DSVR method was found to have slightly reduced errors for the tibiofemoral joint poses, which can be explained by the nature of dual slice registrations. For example, if the center of rotation of a bone is placed on one slice, a slight out-of-plane rotation of the bone would lead to a significant change in the intersection region between the bone and the other slice owing to the inter-slice distance, giving the high sensitivity of the objective function to the out-of-plane rotations.

Figure:



Caption: Fig. 1: The bias and precision of the DSVR measurements of the tibiofemoral and patellofemoral joint poses.

Conclusion: A new non-invasive method based on dual slice real-time MRI was developed and evaluated for accuracies in measuring *in vivo* the 3D poses of the tibiofemoral and patellofemoral joints. With the accuracies achieved, and without the use of ionizing radiation, the proposed method promises to be a valuable tool for studying 3D kinematics of the knee joint in a non-invasive way.

PO-0213

INVESTIGATING THE OCULAR SURFACE TEMPERATURE IN PRESENCE OF UVEAL LESIONS

Sara Matteoli [1,*] Giulia Pieretti [2] Cinzia Mazzini [2] Andrea Corvi [1]

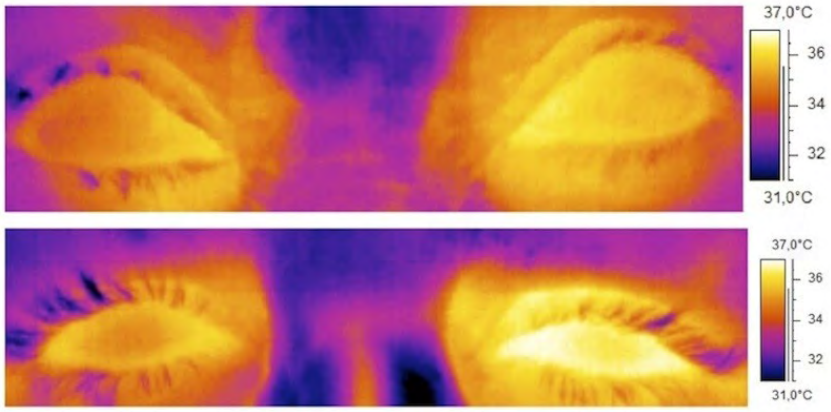
[1]Department of Industrial Engineering, [2]Department of Translational Surgery and Medicine, University of Florence, Florence, Italy

Introduction and Objectives: The presence of a tumor inside biological bodies is known to cause an increase in the temperature of the surrounding healthy tissues [1]. Such phenomena have been observed in the human breast and skin [1]. In the field of ophthalmology, the effects of tumor on the ocular temperature distribution appear to be rarely investigated [2-4]. So far, the use of ocular thermography has offered great opportunities for both monitoring the temperature of the anterior eye and analyzing the effects of some pathology in the OST [5-9]. The aims of this study were to evaluate the ocular surface temperature (OST) in patients affected by uveal lesions and to investigate any correspondence between OST and uveal lesions.

Methods: Nineteen (9M/10F, 30-91 years) affected by uveal lesions were included in the study. Table 1 shows the lesion characteristics of all subjects. They all underwent a comprehensive clinical evaluation in order to investigate the presence of other ocular or systemic pathologies other than uveal lesions. All eyes were investigated by infrared thermography (FLIR A320) and ultrasound. Specifically, the ultrasound scans were always performed after thermography as both dilating drops and acoustic gel could interfere with the temperature measurement. In case of malignant lesions, thermographic acquisitions were performed even after treatment, if given. OST values were calculated by means of an image processing technique, which allowed extracting the OST from the selected frames independently of the eye geometry. This kind of normalization allowed avoiding confounding factors when comparing both eyes of the same subject.

Results: The analysis of the OST showed that patients affected by primary or secondary choroidal melanoma had the pathological eye warmer (0.5-2°C) than the contralateral healthy one. Moreover, the treatment lowered the OST of the affected eye (up to 0.9°C). This effect was shown also in case of treated choroidal hemangioma. In case of choroidal nevi, the OST of the affected eyes were always lower than the contralateral.

Figure:



Caption: Choroidal nevus (right eye, up); choroidal metastasis (left eye, low).

Conclusion: The main hypothesis of this study was to find a temperature increase in case of malignant lesions. This hypothesis was satisfied within the investigated subjects. Indeed, patients affected by choroidal melanoma had the pathological eye warmer than the opposite healthy one. Especially in case of suspect melanoma, this finding may help the clinician to be more suspicious about the malignant nature of the lesion, as its diagnosis was still uncertain. Patients who underwent thermographic measurements after treatment showed, as expected, a decrease in temperature in the treated eye, which can demonstrate a reduced blood perfusion to the lesion (reduced in dimensions itself). The OST measurements may represent a cheap, not-invasive and not-time-consuming test to evaluate ocular vaso-regulation, and to relate those measurements with the presence of intra ocular uveal lesions. This approach paves the way to make thermography a useful tool in differentiating benign from malignant lesions.

DEVELOPMENT AND IMPLEMENTATION OF A METHOD USING OPENSIM TO CALCULATE GLENOHUMERAL JOINT CONTACT FORCE DURING MANUAL WHEELCHAIR PROPULSION ACCESSIBILITY TASKS

Andrew Symonds [1,*] Stephen Taylor [1] Tatsuto Suzuki [2] Peter Smitham [3] Angela Gall [4] Catherine Holloway [2]

[1]Biomedical Engineering, [2]Civil, Environmental & Geomatic Engineering, [3]Orthopaedic Surgery, University College London, [4]London Spinal Cord Injury Centre, Royal National Orthopaedic Hospital NHS Trust, London, United Kingdom

Introduction and Objectives: Manual wheelchair propulsion is known to cause shoulder injury, with repetitive joint loading and a high level of muscle activity suggested as causative factors [1]. High Glenohumeral (GH) joint contact forces during ramp propulsion and weight relief manoeuvres have been reported [2]. Further work is required to investigate the demand placed on the shoulder joint during accessibility tasks including propulsion on cross slopes and ascending bus access ramps. The aim of this study was to develop and test a method of collecting experimental data from wheelchair users during accessibility tasks, to enable calculation of GH joint contact force using OpenSim musculoskeletal modelling software. The methods of data collection chosen reflect the aim to enable analysis of such tasks away from the laboratory setting.

Methods: An experienced Spinal Cord Injured (SCI) manual wheelchair user (L1 incomplete, 75kg body weight (BW)) attended University College London's Pedestrian Accessibility and Movement Environment Laboratory. The laboratory houses an adjustable platform which enables the set-up of accessibility challenges similar to those experienced by manual wheelchair users in the built environment. The participant was required to propel a manual wheelchair on a stretch of level paving, a 2.5% cross slope (wheelchair tilted to the left when moving forwards), 6.5% incline and 12% incline. The 12% incline was set to recreate the length and slope of a London Bus access ramp.

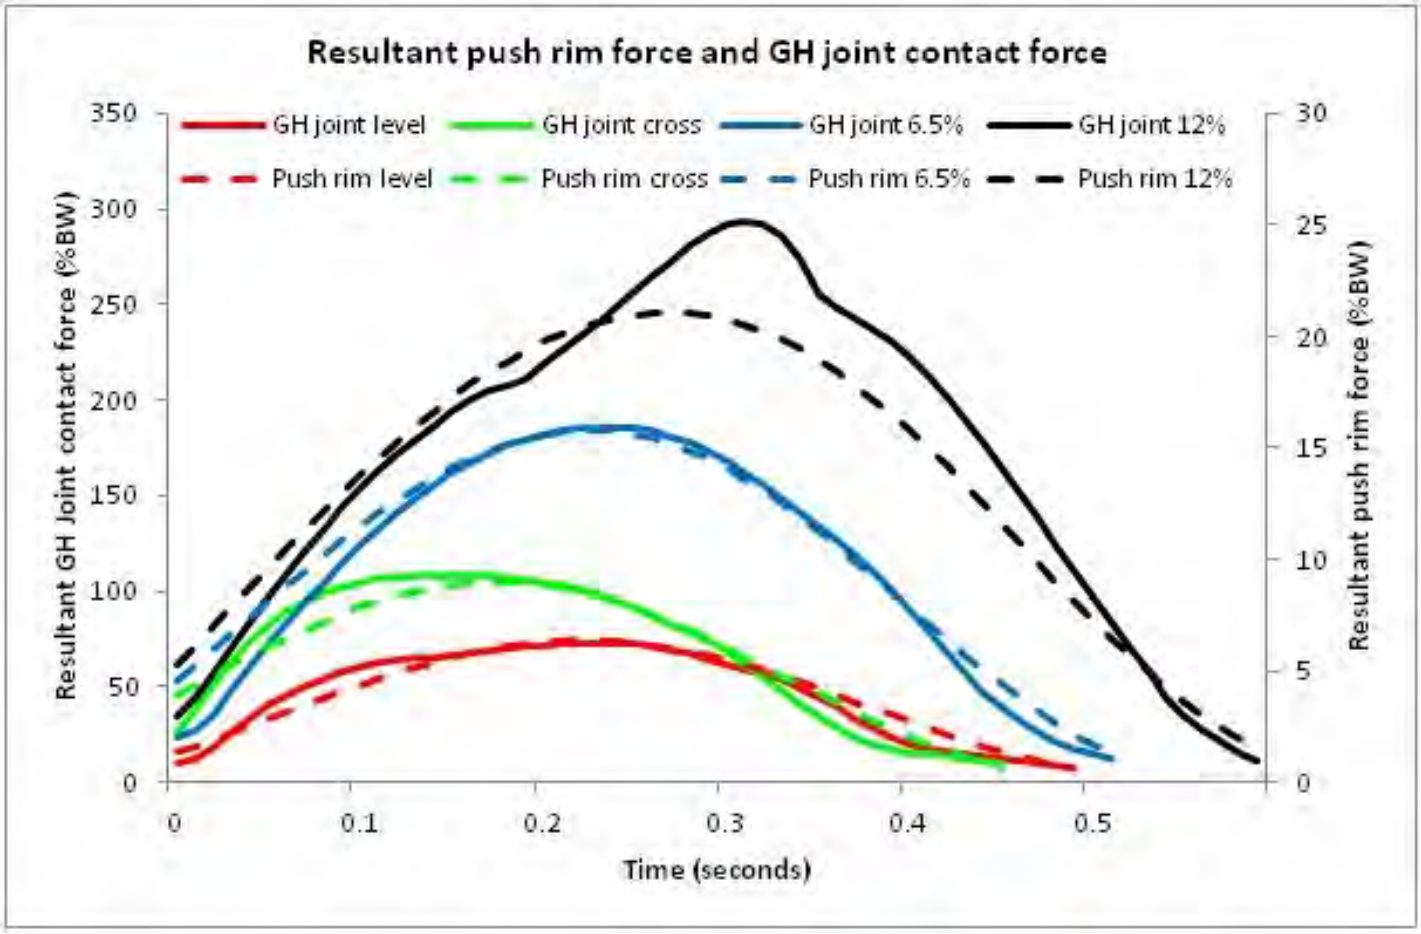
Trunk, left shoulder and elbow kinematics were obtained using the XSens MTw system. Euler angles to animate the model coordinates were derived from the rotation matrix that determined the relative position of XSens units on adjacent body segments either side of the joint [3]. Push rim kinetics were recorded on the left side using the Sensewheel, a lightweight instrumented wheelchair wheel measuring 3-dimensional force, and moment about the wheel axle.

Measured joint kinematics and push rim reaction forces were applied to an adapted OpenSim model of the upper limb and trunk named 'Dynamic Arms 2013', a version of the Stanford VA Upper Extremity Model [4]. The model consists of rigid bodies representing the trunk, upper arm, forearm and hand and was constrained to allow trunk lean, 3 degrees of freedom at the GH joint and flexion/extension at the elbow joint. The actuator set comprised 29 muscles crossing the GH and elbow joints. A reserve actuator was added to the thorax ground joint; otherwise all other model muscle properties were maintained.

The model was manually scaled to participant characteristics. The muscle forces required to generate joint torques were calculated using the OpenSim (Version 3.1) static optimisation analysis, which utilises an objective function that minimises muscle activation. The results of the static optimisation analysis were used to calculate shoulder joint contact force during a representative push phase for each of the conditions. The peak and mean resultant propulsion force and GH joint contact force, and force magnification ratio were calculated [5].

Results: The results from the single SCI participant show that increasing peak and mean resultant propulsion force resulted in an increase in peak and mean GH Joint contact force (Table 1, Figure 1). The contact force results for the level condition were similar to those previously reported involving similar propulsion forces [6]. Increasing forces occurred as the slope of the footway increased.

Figure:



Caption: Figure 1: Resultant push rim and GH Joint contact forces from a representative push phase during different conditions

Conclusion: The experimental method used enabled calculation of GH joint contact force during activities representing accessibility challenges for manual wheelchair users. Negotiating the 12% incline representing the bus access ramp resulted in GH joint contact force 4 times greater than during level propulsion. This indicates that great stress is applied to the shoulder during such activities, potentially leading to injury. Analysis of propulsion during functional tasks to enable optimisation of technique is required.

Table:

Condition	Level	2.5% Cross slope	6.5% incline	12% incline
Peak resultant propulsion force (%BW)	6.4	9.0	15.8	21.0
Mean resultant propulsion force (%BW)	4.0	5.9	10.3	13.6
Peak resultant GH Joint contact force (%BW)	73.1	108.4	185.9	294.0
Mean resultant GH Joint contact force (%BW)	46.0	69.2	113.8	168.4
Peak force magnification ratio	14.6	16.5	12.0	14.5

PO-0215

FES SIMULATION TO REDUCE KNEE MEDIAL COMPARTMENT LOADING BASED ON MUSCULOSKELETAL MODELLING

Rui Xu [1] Ziyun Ding [2] Dong Ming [1] Anthony M.J. Bull [2,*]

[1]Department of Biomedical Engineering, Tianjin University, Tianjin, China, [2]Department of Bioengineering, Imperial College London, London, United Kingdom

Introduction and Objectives: Joint loading is believed to contribute to the development of Osteoarthritis (OA). According to the report of National Institute for Health and Care Excellence, knees are the joints most often affected by OA for people over 45 years old. Compared the medial and lateral compartment of the knee, the medial compartment burdens more loading than the lateral one. Therefore, medial knee OA is nearly 10 times more common than lateral knee OA [1]. Quadriceps, Hamstrings and Gastrocnemius are reported to be the main contributors to the knee adduction/abduction moment [2], which is highly related to the medial-lateral force distribution.

Functional Electrical Stimulation (FES) system is a device that can induce a current in specific motor neurons to generate muscle contractions [3]. It's widely used for individuals with Spinal Cord Injury (SCI).

In this study, FES is expected to reduce the medial compartment loading for medial knee OA patients by increasing certain muscle forces. The objective is to verify this expectation using a lower limb musculoskeletal model with two optimisation methods.

Methods: The data used is normal walking data of one subject, including the motion data and the ground reaction force data. The muscle geometry data is from [4]. Two methods were proposed to increase the muscle forces by revising the static optimisation part and they were used to simulate the situation that certain muscles were stimulated by an FES system. The first method is to add a parameter c into the original objective function:

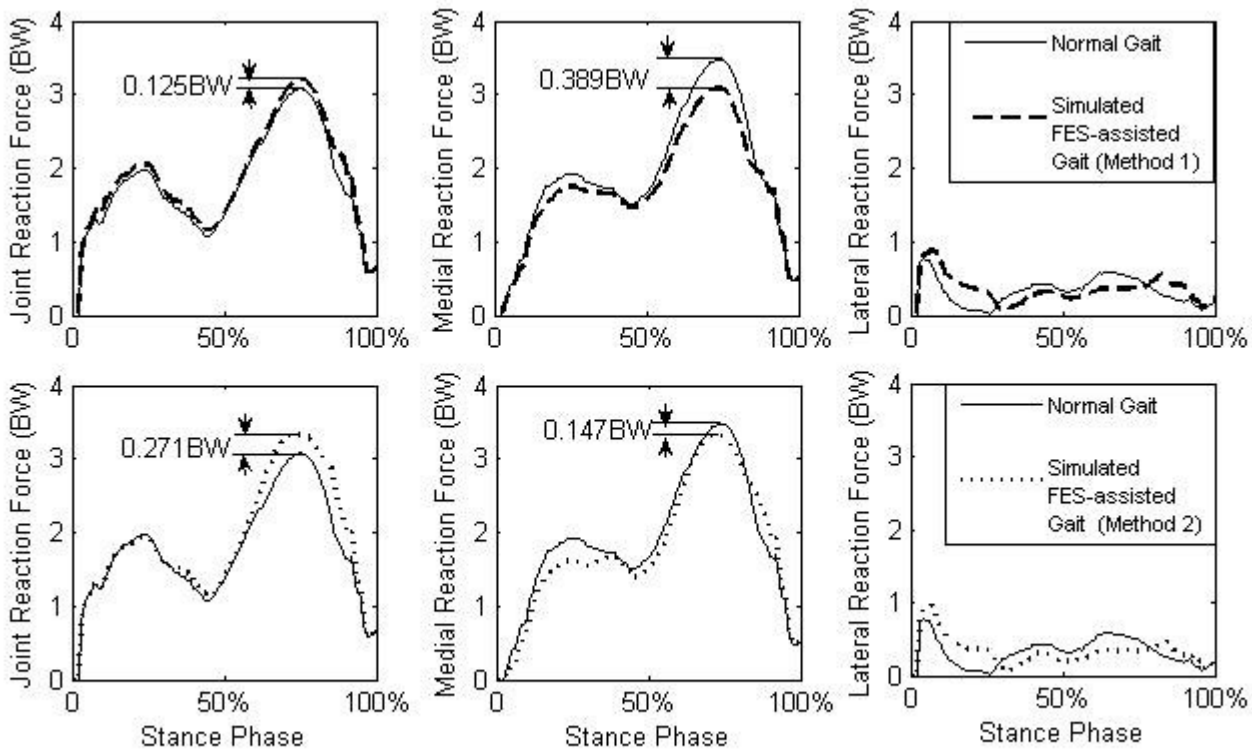
$$\sum(c_i \cdot (f_i/Max_i)^3) \quad (1)$$

where f_i is the muscle force of muscle element i (i=1,…,163) and Max_i is the maximal muscle force of muscle element i. For stimulated muscle elements, c_i=0.25; for others, c_i=1. Compared to the original optimisation without the parameter c, this new optimisation will assign larger forces to the muscles with a smaller c.

The second method is to assume that the muscle forces of the stimulated muscle elements are a (a=1.5) times of the forces obtained by the original model. In this case, the stimulated muscle forces are known parameters for the optimisation.

Results: The knee joint reaction forces during stance phase are shown in the figure. For both methods, the medial reaction forces are effectively reduced 0.389BW and 0.147BW, while the total reaction forces are increased 0.125BW and 0.271BW, respectively.

Figure:



Caption: The comparison of the knee loading of FES simulation

Conclusion: Two methods were proposed based on the lower limb musculoskeletal model to simulate FES-assisted walking. The medial loading of knee can be reduced during FES simulation based on these two methods. The result shows a potential application of FES system to reduce the knee medial forces for medial OA patients. However, more data sets need to be considered and the model will be validated based on obtained EMG data. Furthermore, the stimulated muscles will be analysed in details in order to achieve better results.

COMPARISON OF ACTIVATION PREDICTIONS OF HYBRID FORWARD INVERSE DYNAMICS SIMULATIONS WITH STATIC OPTIMIZATION AND EXPERIMENTAL EMG

Brigitte M. Potvin [1,*] Mohammad S. Shourijeh [2] Kenneth Smale [3] Daniel L. Benoit [2]

[1]Faculty of Engineering, [2]Faculty of Health Sciences, [3]Department of Human Kinetics, University of Ottawa, Ottawa, Canada

Introduction and Objectives: The knee joint is the one most affected by osteoarthritis (OA) and muscluloskeletal modelling and simulations are now starting to be used to better understand the effects of knee injury and OA in order to implement evidence based medical decisions[1,2]. Simulations typically use either inverse or forward dynamics, combined with optimization techniques to solve for muscle redundancy surrounding human joints[3,4]. To solve such a system in a model simulation, optimization is used to minimize predicted muscle activations or metabolic energy expenditure for a given movement. However, these functions may not be applicable in higher intensity motions such as jumping or running, or in individuals with muscle disorders [7]. Using a hybrid forward-inverse dynamics simulation framework could allow for the otherwise costly optimization of muscle model parameters while remaining computationally frugal since it is using the inverse dynamics of the recorded multibody system [5,6]. The purpose of this study was therefore to evaluate the effect of changing the objective function within the hybrid framework by comparing the muscle activation results to those of standard static optimization (SO) and experimental electromyography data (EMG).

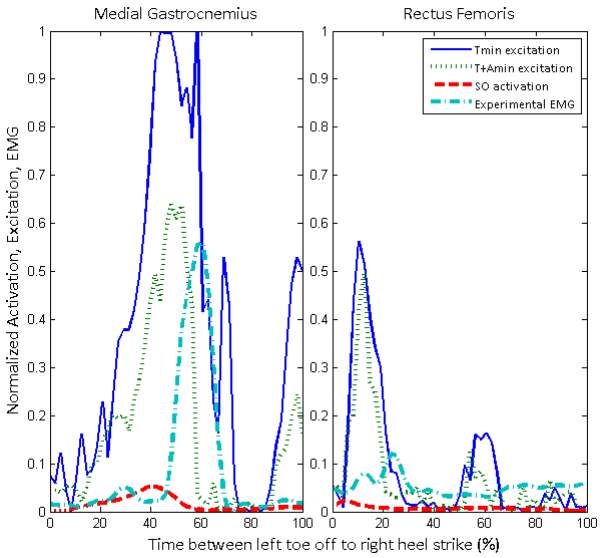
Methods: Kinematic and kinetic analysis data of two healthy young adults (P1: 162cm, 61kg; P2: 185cm, 85kg) performing self-selected pace overground gait were used to run hybrid and inverse dynamics simulations with a simplified musculoskeletal model “gait10dof18musc” available from simtk.org.

We developed a simulation framework which, although similar to the recent Sartori framework [5], also allows any combination of muscle excitations to be treated as known variables (i.e.: from EMG) or unknowns, and the framework is then able to seek optimal excitations using optimization. The objective functions tested in the hybrid framework were minimization of error in torque calculations between the inverse and forward dynamics calculations of the model (Tmin) and of a combination of both minimization of torque error and a physiological cost function, overall muscle activation squared (T+Amin). The inverse dynamics SO process used minimization of total muscle activation squared. Predicted muscle activations from the hybrid simulations were compared to results from the inverse dynamics SO process and to the linear envelope of normalized experimental EMG data from the gluteus maximus(GM), biceps femoris(BF), medial gastrocnemius(MG), rectus femoris(RF), soleus(SL), tibialis anterior(TA) and vastus lateralis(VL). Correlation analyses were used to compare predictions and experimental data.

Results: Tmin hybrid results were generally larger in magnitude than those using the T+Amin cost function (Figure 1). Curve shapes between Tmn and T+Amin results correlated well for the SL (R=0.75 and 0.97), MG (R=0.83 and 0.88), RF (R=0.92 and 0.75) and iliopsoas (R=0.99 and 0.93) muscles for P1 and P2, respectively. EMG profiles of the SL, MG and RF muscles followed those of hybrid results. However the hybrid excitations preceded EMG data despite the EMG being dual-pass filtered, leading to poor correlations. The TA muscle showed a moderate (R=0.45 and 0.37) relationship with

hybrid results, while the gluteus maximus had no correlation or visual trends between any tested conditions or with experimental data. SO results did not follow experimental EMG profiles, but did show visual parallels with the T+Amin hybrid results for the VL and BF muscles, although SO results had smaller value magnitudes.

Figure:



Caption: Figure 1: Examples of predicted muscle excitations (hybrid model) and activations (Inverse dynamics static optimization) in comparison to experimental EMG data for the right medial gastrocnemius and right rectus femoris muscles.

Conclusion: Similarities were found between some muscle predictions from the hybrid framework and experimental EMG data, more so than between static optimization results and EMG. Hybrid results differed when the physiological cost function was added to the torque error. The choice of optimization criterion is important when running musculoskeletal simulations. Modifying this optimization to a more physiologically appropriate goal, as well as increasing the complexity of the modeled knee to include a multiple degree-of-freedom joint and more muscles, could improve model predictions in gait as well as in other motions.

Caption: Figure 1: Examples of predicted muscle excitations (hybrid model) and activations (Inverse dynamics static optimization) in comparison to experimental EMG data for the right medial gastrocnemius and right rectus femoris muscles.

PO-0217

ESTIMATION OF LOWER LIMB MUSCLE FORCES IN CHILDREN'S GAIT

Filipa Joao [1,*] Vera Bagao [1] Silvia Cabral [1] Vera Moniz-Pereira [1] António Veloso [1]

[1] Laboratório de Biomecânica e Morfologia Funcional, CIPER, Faculdade de Motricidade Humana, Universidade de Lisboa, P-1499-002 Cruz Quebrada, Portugal

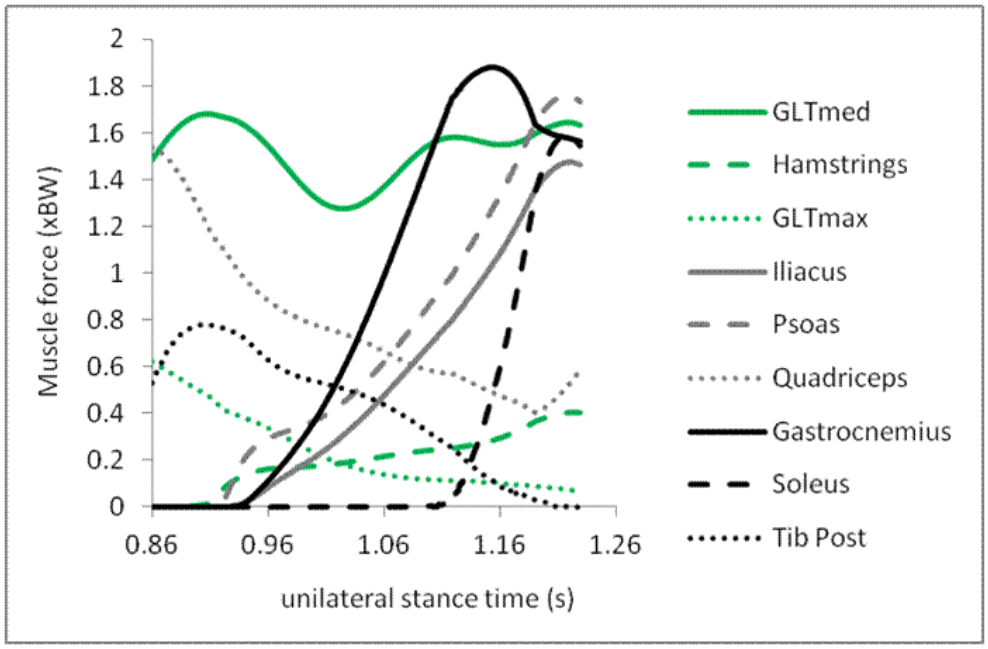
Introduction and Objectives: Pathological walking patterns are frequently assessed in children with different gait abnormalities. The observed gait patterns are the result of the forces generated by the muscle-tendon unit structures, which drive the skeletal to a certain motion. However, these internal forces are not trivial to quantify. Moreover, the lower limb muscle forces estimation in children is scarcely reported[1,2]. In order to better understand these gait deviations from the normal pattern, a normative database of the pediatric population should be used for correct comparison. Therefore, the aim of this study was to estimate the individual muscle forces of the lower limb during gait in normal children, in order to create the normative database for our laboratory.

Methods: The gait data from ten children (5 male, 5 female, age: 7.5±0.8 yrs old and mass: 27.06±5.42 kg) were analyzed for this study. Motion capture was collected using an optoeletronic system of 14 cameras Qualisys (Oqus-300) operating at 100Hz. 17 reflective markers and 4 marker clusters were used for the reconstruction of eight body segments (trunk, pelvis, thighs, shanks and feet). Ground reaction force (GRF) was collected with 3 force plates and joint moments were calculated by inverse dynamics. Kinematic and kinetic data were processed with a lowpass Butterworth filter with a cut off frequency of 6 Hz. All data processing and model building were done in Visual 3D. Electromyography (EMG) was collected for the gluteus medius, rectus femoris, semitendinousus, gastrocnemius lateralis and tibialis anterior. The EMG was highpass filtered (Butterworth with a frequency cut of 30Hz) and a linear envelope (moving frame of 51) was applied. All children walked at their self-selected speed and the analyzed gait periods were selected from the cycles where the subjects achieved two consecutive force plate strikes during which only one foot contacted each force plate. A generic musculoskeletal model with 19 degrees of freedom and actuated by 92 Hill-type muscle-tendon units[3,4] was scaled to match the anthropometric characteristics of the subjects. Subtalar and metatarsophalangeal joints remained at neutral angular position. Residuals reduction was performed to compensate for dynamic inconsistencies between the measured kinematics and ground reaction forces. Individual muscle forces and activations were estimated using a static optimization algorithm[4] during the unilateral stance (USt) period corresponding to the time interval from 10% to 50% of the gait cycle. All muscle forces were normalized to each subject body weight (BW). To assess whether muscle activations estimated in the static optimization were similar to the subjects EMG activity, we visually compared them with the experimentally obtained EMG.

Results: In order to facilitate the muscle force analysis we grouped some of the model actuators: the 3 vasti and rectus femoris (Quadriceps); the semitendinosus, semimebranosus and biceps femoris (Hamstrings); the gastrocnemius medialis and lateralis (Gastrocnemius); the 3 actuators of the gluteus maximus (GLTmax) and the 3 actuators of the gluteus medius (GLT med). We have selected only the muscles which generated force above 0.4 BW and the results are presented in xBW ± SD. We observed that during the initial USt period, the GLTmed, Quadriceps, GLTmax and Tibialis

Posterior exerted the greatest amounts of force, reaching 1.72±0.45 BW, 1.25±0.42 BW, 0.58±0.17 BW and 0.90±0.53 BW respectively. From the middle period until the end, the hip flexors (psoas and iliacus), gastrocnemius and hamstrings increased their force production, generating a peak force of 1.04±0.40 BW, 0.90±0.34 BW, 1.89±0.36 BW and 0.44±0.13 BW, respectively. Soleus muscle generated a force peak of 1.74±0.38 BW in the final phase of the USt (see Fig.1 for a representative subject).

Figure:



Caption: Fig.1 - Estimated muscle forces of one representative subject

Conclusion: The estimated muscle forces and activations show similar patterns to the collected EMG of some of the muscles (especially gastrocnemius, rectus femoris and GLT med). Our results are in accordance with the studies that report muscle force in children with the same age[1,2]. This indicator give us confidence for the next step, that is to use these estimated muscle forces to calculate the joint reaction forces at the hip, knee and ankle joints and also the contribution of each muscle to accelerate the body forward during locomotion (induced acceleration analysis). It is also in process the increasing of the normative children's gait database which will allow us to establish the comparison between the normal and different types of abnormal gait. **Acknowledgments**: this work was supported by CIPER-FCT (project: PEst-OE/SAU/UI447/2014).

IMPROVED CONTACT AND MENISCUS PROPERTIES IN MULTIBODY DYNAMICS MODELING OF THE KNEE

Stephen Wilson [1] Jerome Hausselle [1,*] Trent Guess [2] Roger Gonzalez [1]

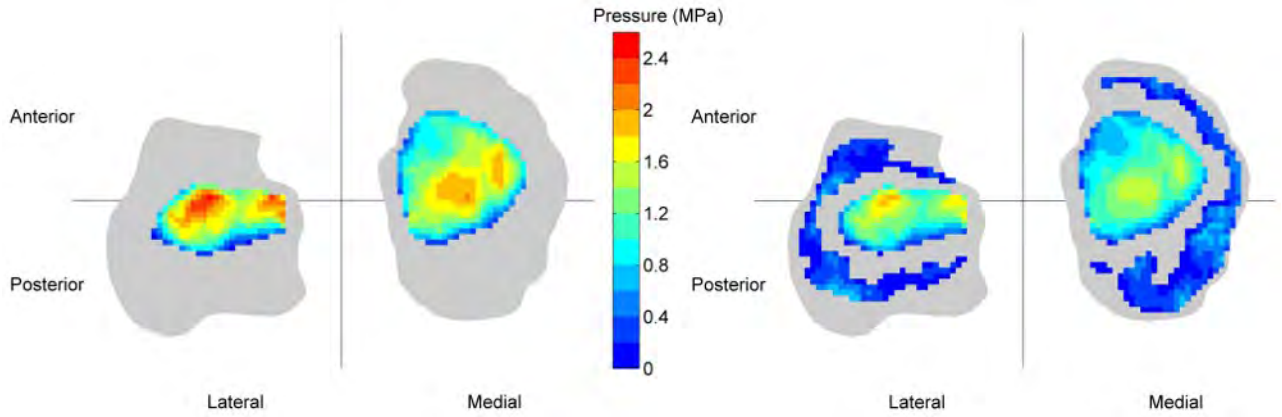
[1]Mechanical Engineering, University of Texas at El Paso, El Paso, [2]Physical Therapy, University of Missouri, Columbia, United States

Introduction and Objectives: Understanding knee joint biomechanics during daily activities is a critical step towards preventing degeneration. Since *in vivo* measurements are very difficult to perform, computer models are a popular method to achieve this understanding. One of the largest barriers to progress in this area is the high developmental and computational cost required by finite element models which include meniscus and simulate dynamic motions with multiple contacts. Although less popular than finite element modeling, multibody dynamics modeling is another approach and shows promise since multibody models do not require time-consuming meshing steps and are less computationally expensive. Guess et al. [1] have developed a meniscus model that includes radial deformation. However, meniscus material properties were optimized to match a finite element solution, which is undesirable for a method meant to capitalize on efficiency. Although, cartilage-to-cartilage contact parameters have also been implemented [2], they suffer from being imprecise for cartilage-to-cartilage contact and optimization-based for cartilage-to-meniscus contact. The current work addresses these issues while studying vertical loading of a straight knee joint with and without menisci.

Methods: A knee model was constructed in MSC Adams (Newport Beach, California) using geometries derived from magnetic resonance images of a cadaver specimen. We implemented an Adams routine to segment the menisci cirumferentially by 15deg increment relative to meniscus volume centroid and implement specific physically-based stress-strain equations between adjacent meniscus segments. Horn attachments were modeled using a translational spring with a stiffness of 180N/mm [3], whereas corronary ligaments that connect the tibia to the meniscus element closest to the collateral ligament path were modeled using a translational spring with a stiffness of 50N/mm. Stress-strain equations for the menisci were taken from Moran [4]. A custom contact subroutine was implemented which calculates contact forces from contact strains and areas using a physically-based third-order stress-strain polynomial relationship for each of the two contacting bodies of interest. Stress-strain polynomials for tibial and femoral cartilage were computed from values recommended by Deneweth [5]. The menisci stress-strain polynomial equation was determined from Moran [4]. All degrees of freedom were constrained except vertical displacement and a compressive load of 1000 Newtons applied to the knee with and without menisci.

Results: Addition of the mensici greatly increased contact area and thus noticably reduced peak and overall pressure (see figure). Results are similar to experimental findings by Fukubayashi and Kurosawa [6,7] (see table). However, they found smaller contact area without menisci and thus had higher average and peak pressures. This could be due to individual geometry variance and the use of generalized and non-region-specific cartilage and mensicus material parameters. Peak pressure in the current model could also be lower due to contact being discretized into 3x3mm elements.

Figure:



Caption: Pressure map of tibial cartilage during 1000N vertical load with (right) and without (left) menisci.

Conclusion:

Multbody dynamics modeling of the knee has relied on oversimplified material properties which require optimization. In the current model, we implemented experimentally determined mechanical equations to better simulate contact and meniscus properties. This work is a promising development which enables efficient simulation of the consequences of cartilage and mensicus degeneration during a variety of daily activities.

Table:

	Without Menisci		With Menisci	
	Model	Experimental [6,7]	Model	Experimental [6,7]
Contact area/Total area	38%	26%	64%	62%
Average Pressure (MPa)	1.27	1.97 ± 0.56	0.71	0.8 ± 0.2
Peak Pressure (MPa)	2.41	6	1.93	2-3

PO-0219

DEVELOPMENT OF A SUBJECT-SPECIFIC THREE-DIMENSIONAL WHOLE-BODY MODEL TO PREDICT HUMAN WALKING

Dan Hu [1,*] David Howard [2] Lei Ren [1]

[1]Mechanical Aerospace and Civil Engineering, University of Manchester, Manchester, [2]Computing Science and Engineering, University of Salford, Salford, United Kingdom

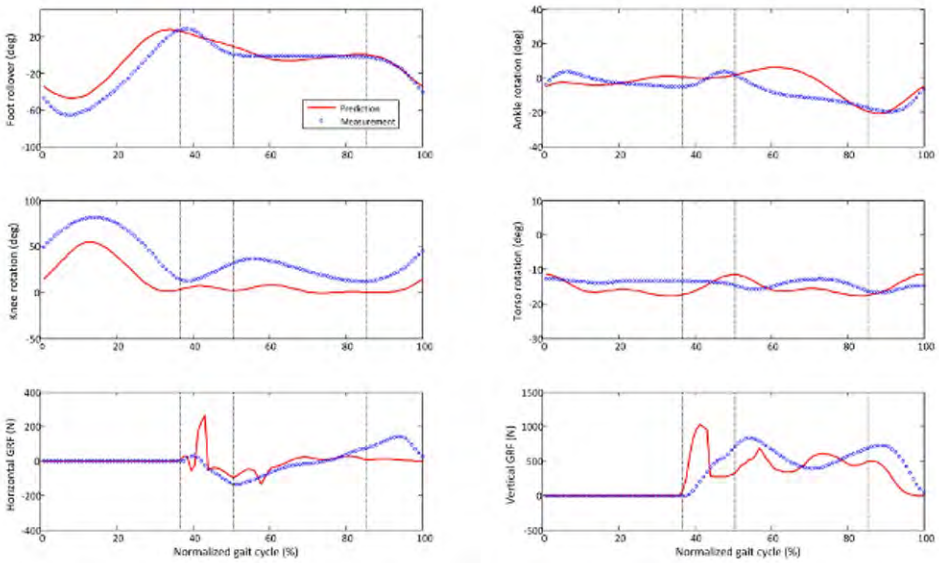
Introduction and Objectives: Over the past decades, intensive studies have been carried out toward an understanding of the biomechanics of human walking using state-of-the-art three-dimensional (3D) motion analysis and biomechanical modelling techniques. Although these studies have greatly deepened our understanding of the biomechanical mechanisms underlying human walking, the majority of the outcomes have been descriptive in nature as they are based on measurements, which by its very nature tells us what happens but not why it happens. Very few studies have been devoted to predictive modelling (i.e. not based on measurements), which has the powerful feature of being explanatory because the reasons for particular model behaviours can be interrogated [1,2]. The objective of this study is to develop a 3D subject-specific 3D whole-body human model to predict walking kinematics and kinetics with minimal measurement inputs.

Methods: A 3D whole-body multi-segment model was constructed consisting of 13 segments (head, torso, pelvis, right and left upper arms and forearms, right and left thighs, shanks and feet) with total 25 degree of freedoms (DoFs). Three-dimensional whole-body gait measurement for a healthy male subject (age: 25; weight: 68.8kg; height: 177cm) was conducted to support and validate the modelling. The anthropometric data of the model were estimated based on the test data collected in the gait measurement. The subject-specific positions and axis orientations of the anatomical joints in the model were defined using the functional method conducted in the gait measurement. Quaternions were used to define the 3D motions of each joint, of which the time traces were represented by using parameterised spline curves. In the model, the feet were represented as effective rollover components over the ground surface without slipping. The 3D kinetics of the whole-body system was evaluated using a 3D inverse dynamics approach. In this study, the human walking behaviour was formulated as an optimal control problem by minimising certain criteria whilst subjected to multiple constraints. Those kinematic and kinetic constraints define human walking include joint motion range, segment motion range, swinging leg condition, stance leg condition, double support condition, ground reaction force and moment condition and task constraints etc.

Results: The optimization simulations were implemented in MATLAB programming environment. Three gait parameters: average walking velocity, gait cycle period and double stance duration were used as the only inputs to drive the model. In the current stage, we set the ankle, knee, hip and waist joins to move freely in the sagittal plane with the shoulder, elbow and neck in their neutral standing positions, and minimising the mechanical energy cost was used as the criterion. The predicted lower limb joint motions and ground reaction forces were compared to the measurement data (see Figure 1). Over most of the gait cycle, the predicted results are in reasonably good agreement with the measured data. The predicted mechanical energy expenditure for the whole gait cycle was 229.65 J, which was close to the previous result [2].

However, there are still some discrepancies between the prediction results and measurement data especially torso rotations, which may be because that the model was confined to the sagittal plane and the upper limb motions were neglected.

Figure:



Caption: Figure 1 Predicted rotations of the right foot rollover, right ankle, right knee and torso in the sagittal plane (red line), compared with measured data (blue point) for one subject (age: 25; weight: 68.8kg; height: 177cm); Predicted horizontal and vertical ground reaction force (GRF) (red line), compared with recorded force plate data (blue point) for the subject.

Conclusion: In this study, we have established a computational framework to predict the 3D whole-body human walking based only on three simple gait descriptors. Promising results have been achieved in terms of predicted joint motions and ground reaction forces compared with the measurement data. Future work involves the 3D whole-body simulations by releasing all the joint motions in all the three planes, and also by introducing multiple criteria into the optimisation scheme.

THE AFFECT OF BODY SEGMENT PARAMETER CHOICE ON ESTIMATES OF INTERNAL WORK IN A TOTAL BODY ACTION.

Gary Doyle [1,*] Wendy Drechsler [1] Ryan Mahaffey [1] Mary Cramp [2]

[1]School of Health, Sport and Bioscience, University of East London, London, [2]HAS - Allied Health Professions, University of the West of England, Bristol, United Kingdom

Introduction and Objectives: Internal work is estimated by the change in kinetic energy from the velocity and mass of a given system and is suggested as a descriptor of movement proficiency [1]. Whilst the internal work estimates are influenced by the chosen body segment parameter (BSP) data set there is little research examining how this choice influences the results.

Regression based BSPs are often used due to simplicity and time constraints. Dempster's [2] data is commonly used but has a small sample size based on an elderly population. de Leva's [3] data set is based on a more recent, larger population, yet is less commonly used. These data sets differ in their values for segmental mass, position of centre of mass and moment of inertia.

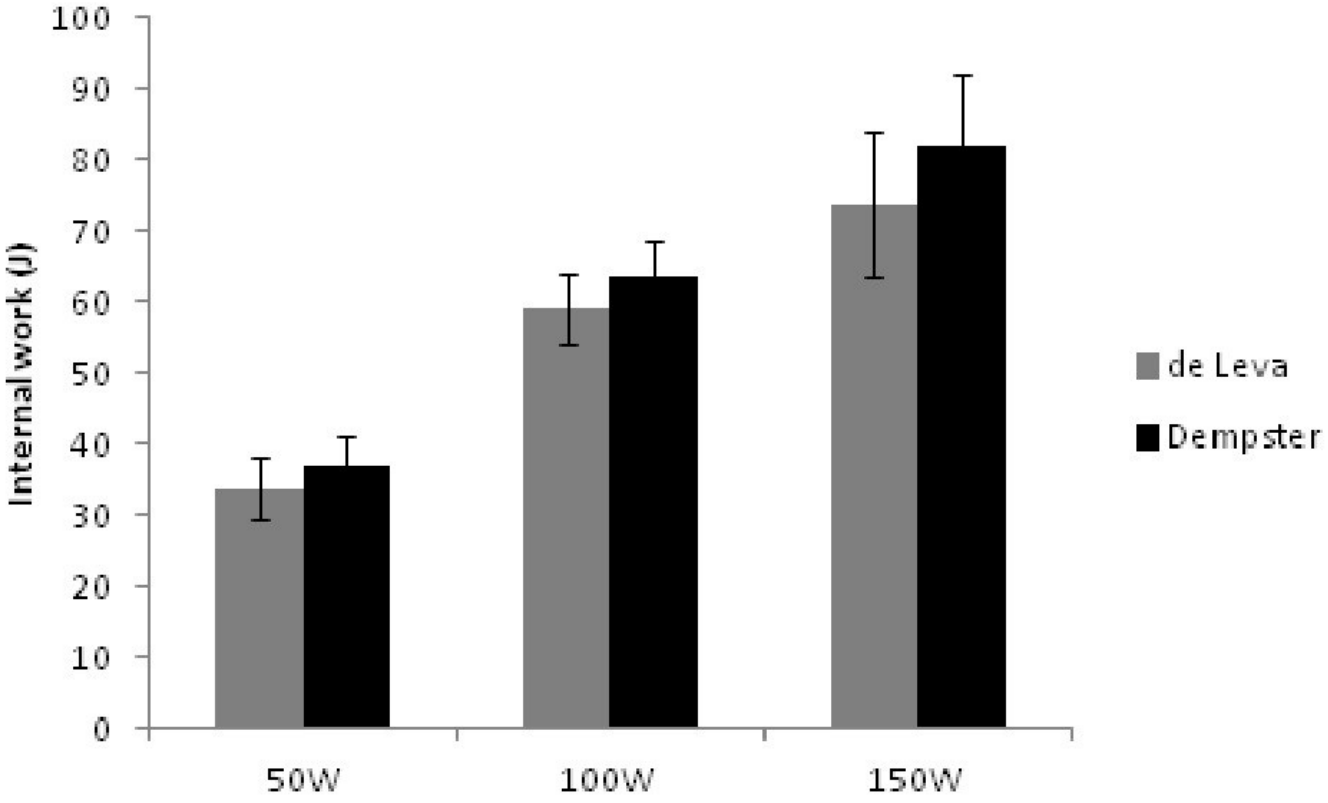
The aim of the research was to examine the differences and repeatability in calculated values of internal work for two different BSP data sets using the same kinematic data on a total body movement at different exercise intensities.

Methods:

Ten male participants (mass 81±7 kg; stature1.77±0.06 m, age 31±8 yrs) familiar with a rowing ergometer but without formal training volunteered and rowed at 50,100 and 150 W, within a three-dimensional motion capture system (Vicon, OMG, Oxford). From the Vicon Plug-in-Gait model, joint centres position, with respect to time, were exported to a custom written LabVIEW code (National Instruments) for the drive phase of 8 strokes, at each intensity. From a 13 segment body, internal work was calculated as the change in translational and rotational kinetic energy from the start to the finish of the drive phase of the stroke data and were analysed using both the data sets of Dempster [2] and de Leva [3]. Intra-trial repeatability was assessed using Intraclass Correlation Coefficients (ICC). Statistical differences were assessed using pairwise comparisons and effect sizes (Cohen's *d*).

Results: Internal work data was normally distributed and considered reliable (ICC 2,1 > 0.7). Internal work increased with respect to exercise intensity. The mean difference in work done with respect to intensity was 3.0 J, 4.6 J and 8.0 J for 50 W, 100 W and 150 W, respectively, representing changes in internal work between BSP data sets approaching 10%. The Dempster condition demonstrated larger estimates and variability of internal work, at all intensities (see table 1). Statistical differences ($p<0.05$) between the de Leva and Dempster conditions at each intensity were supported with moderate to large effect sizes (Cohen's $d = 0.48, 0.30, 0.8$, respectively).

Figure:



Caption: Figure 1 Average internal work against rowing intensityfor each BSP

Conclusion:

Identical kinematic data for a total body action was modelled with two different BSP data sets across 3 exercise intensities, to examine the effects of calculations of internal work. The differences approximated 8-10%, were statistically different and were supported by moderate to large effect size statistics which may indicate some importance to the results of mechanical calculations. However, the overlap of confidence intervals suggested little difference to the sample variability for internal work between the two models.

It is not possible to suggest that one BSP data set yielded more accurate results than the other. However, the ability of models to predict outcomes is based on the assumptions used. Whilst de Leva (1996) data set, which is based on a larger cohort, and was completed on more recently living participants returned smaller values of internal work, it demonstrated less variability in the results which is attributed to the differences segmental mass, position of centre of mass and moment of inertia between data sets.

The results of this study indicate small but potentially important differences in internal work calculations dependent upon choice of data set. Careful consideration of the BSP data sets needs to be given when calculating internal work matching the participants with the regression cohort.

Table:

	Mean (J)	95% CI	SD	$ICC_{(2,1)}$	SEM
de Leva 50W	33.8	4.40	5.8	0.78	2.72
Dempster 50W	36.8	4.98	6.4	0.80	2.90
de Leva 100W	59.1	10.07	14.0	0.92	4.08
Dempster 100W	63.7	11.46	16.6	0.91	5.10
de Leva 150W	73.8	12.09	9.3	0.70	5.06
Dempster 150W	81.8	13.64	10.7	0.71	5.83

DEVELOPMENT OF MOLECULAR-BASED NON-LINEAR VISCOELASTIC MODEL OF COLLAGEN FIBRILS

Andrzej Mlyniec [1,*] Tadeusz Uhl [1]

[1]Department of Robotics and Mechatronics, AGH-University of Science and Technology, Krakow, Poland

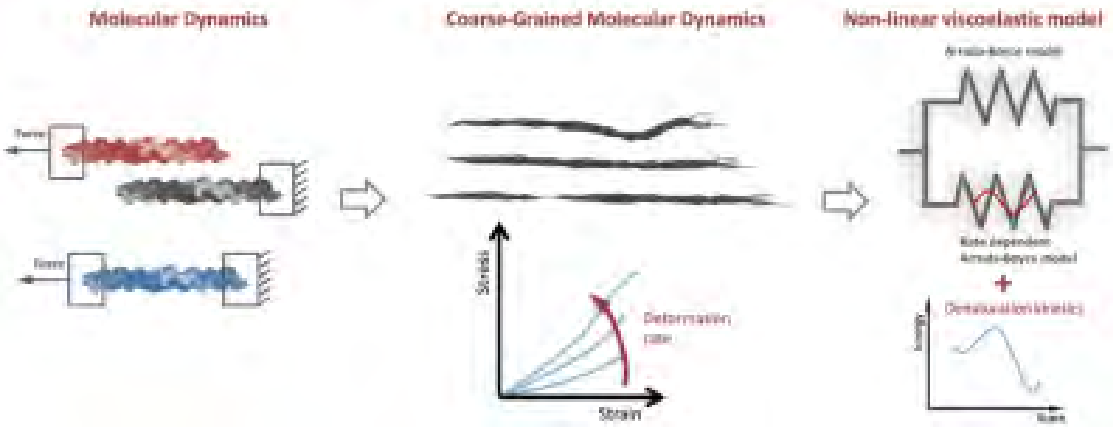
Introduction and Objectives: Collagen is the most abundant protein in mammals. Biomechanical properties of fibrous collagenous tissues result from the molecular structure of collagen fibrils. Collagen fibrils consist of staggered array of tropocollagens, connected to each other by covalent cross-links as well as hydrogen bonds. The viscous friction mediated by the hydrogen bonds results in fibril stiffening with the increase of the loading rate. This effect known as a collagen viscoelasticity can be studied by means of Molecular Dynamics (MD) simulations [1], although predicted by MD values of elastic moduli are overestimated. This results from extreme high loading rates and very short simulation times. The temporal and spatial limitations of atomistic methods can be partially overcome by the use of Coarse-Grained model [2–4], but predicted stress-strain curves still do not correspond to the behavior at a macro-scale.

The goal of our study is to create the molecular-based viscoelastic material model which can be directly used in Finite Element Analysis of collagenous tissues. Moreover, we aim to enhance our model by denaturation kinetics. This allow to predict the influence of thermal denaturation on biomechanical behavior of collagen fibrils.

Methods: The molecular models were built using the collagen-like peptide structure obtained with X-ray diffraction. For this model we performed shear and tensile tests, which were used for calibrating parameters of Coarse-Grained (CG) model. Using this CG model we created a fibril model incorporating three-dimensional staggered array of tropocollagens (Fig.1). Created CG models were used to investigate the viscoelastic behavior of collagen fibrils, resulting from hydrogen bonds network [4]. Results of meso-scale CG analysis have been used to calibrate the non-linear viscoelastic model which consist of hyperelastic Arruda-Boyce model and rate dependent Arruda-Boyce model disposed parallel (Fig.1). Moreover, proposed model has been enhanced by reaction kinetics using Arrhenius equation. This enhancement allow one to predict influence of thermal treatment on mechanical behavior of collagen fibrils.

Results: The proposed nonlinear viscoelastic model allow to predict mechanical behavior of collagen fibrils for deformation rates ranging from 0.1 to 1e9. Additionally, incorporation of denaturation kinetics in constitutive model, has allowed to predict drop of mechanical properties resulting from thermal treatment. Elevated temperature leads to decrease of elastic behavior as well as decrease of viscoelasticity of the fibrils. Predicted values of Young's modulus are in good quantitative agreement with results of experimental observations[5-6].

Figure:



Caption: Modeling methods used in development of molecular-based nonlnear viscoelastic model

Conclusion: The proposed model allows to predict biomechanical behavior for real deformation rates, thus can be successfully used in micro Finite Element modeling or other homogenization methods [7]. Our model takes into account changes of rigidity as well as viscosity of the fibers exposed to elevated temperatures. The thermal cleavage of collagen leads to reduced influence of a deformation rate on the fibrils stiffness. Further development of proposed constitutive model includes taking into account influence of the proteoglycans and elastin as well as external loading.

MODELING PARAMETERS TO CALCULATE REALISTIC INVERSE DYNAMICS MUSCULAR ACTIVITY IN RUNNING

Allison H. Gruber [1,*] Ross Miller [2] Brian Umberger [3] Shane Murphy [1] Joseph Hamill [3]

[1]Kinesiology, Indiana University Bloomington, Bloomington, [2]Kinesiology, University of Maryland, College Park, [3]Kinesiology, University of Massachusetts, Amherst, United States

Introduction and Objectives: Modeling parameters, such as tendon slack length (Lslack), maximum isometric force production (Fmax) and series elastic strain at maximum isometric force production (Umax), are typically taken from experimentally measured values of cadavers or non-human mammalian muscle tissue. Modeling parameters from those sources often result in simulated activation of the plantar flexors over 1.0 when modeling muscle-tendon mechanics from experimental inverse dynamics data. One solution is to increase Fmax to account for the difference in muscle size between elderly cadavers and healthy, young subjects performing dynamic tasks. Although adjusting parameter values can allow for simulated muscle forces to correspond with experimental joint moments produced in running, the resulting muscle-tendon dynamics comparable to ultrasound measurements [1]. Purpose: to examine the sensitivity of gastrocnemius (GAS) muscle activation in running estimated from inverse dynamics to muscle model parameters, and determine parameter ranges that predict realistic activations.

Methods: Eighteen rearfoot runners (26.8±6.3 yr, 71.3±9.2 kg, 1.8±0.1 m) ran at a target speed of 3.5 m•s^{-1} ±5% as 3D kinematics and ground reaction forces were collected and processed into sagittal plane knee angle, ankle angle, and resultant ankle moment. GAS muscle-tendon unit (MTU) length, velocity, and moment arm were estimated from the joint angles [2]. GAS muscle force was calculated assuming ~34.5% of the active joint moment was attributed to the GAS then dividing the GAS moment by the GAS moment arm. A two-element Hill muscle model was used to determine the GAS contractile element (CE) and the series elastic element (SEE) lengths and velocities. Activation (Act) was then calculated as a function of the instantaneous CE force, length, and velocity. This calculated was repeated with Fmax values adjusted by changing the specific tension (ST) from 10-100 N•cm^{-2} in 10 N•cm^{-2} increments, and with Umax values adjusted in 1% increments from 3%>10% at each level of Fmax. When Umax was changed, Lslack was adjusted to maintain a constant ankle angle at which the maximum isometric moment was produced. The CE and SEE kinematics of simulations that resulted in a maximum act <1.0 were compared with literature values.

Results: 31 simulations resulted in a peak act of <1.0 (ST 40-100; Umax 1%>7%). All but 4/31 simulations resulted in a peak CE shortening velocity less than 8 Lo/s (ST(N•cm^{-2}):Umax(%)= 40:3, 80:3, 90:2, 100:2). Only 5/31 simulations resulted in CE lengths within the range measured with ultrasound (ST(N•cm^{-2}):Umax(%)= 70:3, 80:1, 80:2, 80:6, 90:5)[1].

Conclusion: Lower Umax values resulted in more reasonable simulated GAS activations and CE length simulated with an inverse dynamics-based musculoskeletal model regardless of the specific tension, thus Fmax. These Umax values were slightly lower than the gastrocnemius tendon/aponeurosis strains measured with ultrasound during running [3]. Caution should be made when using higher values for Umax or specific tension to account for parameters measured from cadavers or non-human mammalian muscle.

SCALING MUSCLE PARAMETERS IN A CANINE MUSCULOSKELETAL MODEL.

Billy Dries [1,*] Ilse Jonkers [2] Wim Van den Broeck [3] Walter Dingemanse [1] Ingrid Gielen [4]

[1]Faculty of Veterinary Medicine - Medical Imaging and Small Animals Orthopaedics, University of Gent, Gent, [2]Faculty of Kinesiology and Rehabilitation Sciences - Human Movement Biomechanics Research Group, University of Leuven, Leuven, [3]Faculty of Veterinary Medicine - Department of Morphology, [4]Faculty of Veterinary Medicine - Department of medical imaging and orthopedics of small animals, University of Gent, Gent, Belgium

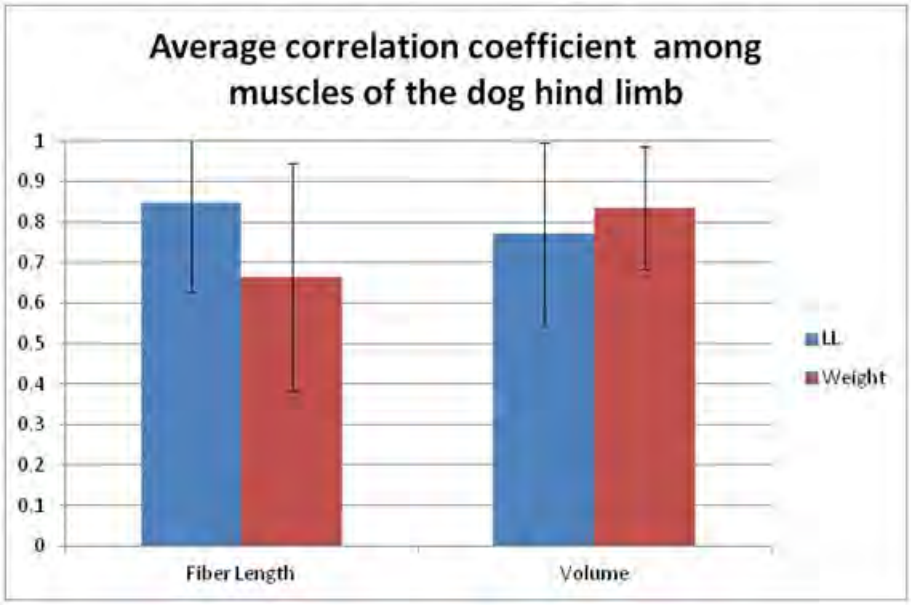
Introduction and Objectives: Recently, veterinary institutions have taken an interest into the possibility of creating musculoskeletal computer models of domestic animals.To use these musculoskeletal models for the analysis of musculoskeletal loading, incorporation of muscle structures is essential. Apart from defining the geometry of the muscle line of action, parameters describing the muscle force generating capacity need to be defined. To do so, experimental measures of optimal fiber length, maximal muscle force, pennation angle and tendon slack length need to be acquired in dogs. Furthermore, a dedicated method for scaling these parameters needs to be established and tested. This study reports on a first data set of optimal fiber length and muscle volume acquired in 3 canine hind limbs and evaluates the use of weight versus limb length (LL) as scaling factor for the muscle-tendon parameters.

Methods: Muscles were dissected from the right hind limb in three dogs weighing 30kg, 35kg and 52kg.
The limb bones were placed caudally on a table and a calibrated photograph was taken. LL was calculated in ImageJ based on the summed length of the individual limb bones.Fat and connective tissue was removed as much as possible without damaging the muscle. Muscles were then weighed on a scale with a sensitivity up to 0,001g. Immediately afterwards the muscles were placed in a neutral-buffered 10% formaldehyde solution for 48-72h, after which they were placed in a 0.4M phosphate-buffered saline solution with a pH of 7.2 for 24-48h. Subsequently muscles were placed in a 20% sulphuric acid solution to loosen the muscle fibers for 3-7 days. Once the muscle fibers were loosened, 3-8 individual muscle fibers (or small bundles of fibers of equal length) were removed, depending on the size of the muscle. Muscle fibers were taken from different sites in the muscle to ensure a representative sample. The extracted muscle fibers were then photographed upon grid paper for scale.The pictures of the muscle fibers were analysed in ImageJ to measure fiber lengths. Fiber length was measured from end to end following the curvature of the fiber.
A correlation matrix using Pearson product moment was constructed to analyse the relationship between the different muscles fiber lengths and volumes with the dogs weight and LL.

Results: There are clear relationships between the LL and weight with both muscle fiber length and muscle volume for at least 70% of the measured canine hind limb muscles. However, these correlations were not clearly more pronounced for LL or weight (fig 1). Nevertheless, muscle fiber length correlated more strongly with LL than with dog weight and inversely muscle volume correlated more strongly with dog weight. The correlation coefficient between LL dog was that strong weight. In specific muscles the fiber length and/or muscle volume correlated negatively with the scaling parameters. For example, the internal obturator fiber length scales and strongly negatively with LL and weight, meaning that a heavier dog with longer limbs would have a shorter muscle fiber in the internal obturator muscle. This is mostly found in very small

and/or short muscles and could be related to measurement error. Therefore, these results were omitted from the calculations.

Figure:



Caption: fig 1: correlation coefficient of muscle fiber length and volume with LL and Weight, averaged over the different muscles of the dog hind limb

Conclusion:

As dogs can vary widely in size and shape, it is important to develop procedures to scale musculoskeletal models for dogs in order to allow sufficient flexibility of the muscle model parameters to adequately represent dogs of different sizes and body proportions. This study evaluated LL based on the hind limb dimensions and weight to normalise hind limb muscle parameters in dogs.

The (relative) weakness of the correlation between dog weight and LL can be expected from the variability in dog body conformations.

Leg length appears a better normalising factor than weight for fiber length, but not for muscle volume. Although LL could not unambiguously be identified as a better normalising factor than weight, there is evidence to suggest that muscle parameters for different muscles may scale differently depending on the scaling factor used. Further research will be needed to investigate how a generic (dimensionless) model may be scaled to fit specific dog breeds.

PROPOSITION OF AN ALGORITHM FOR SIMULATING NATURAL VARIABILITY IN ARM GRASPING POSTURE WHEN ROTATING A SPHERICAL OBJECT

Julien Lardy [1 2] Thomas Robert [2] Xuguang Wang [2,*]

[1]MIP (EA 4334), Université de Nantes, Nantes, [2]LBMC (UMR-T 9406), Ifsttar, Bron, France

Introduction and Objectives: Digital human models are being more and more used in early phase of a product/workplace design. However, human motion simulation still faces the well-known problem of motor redundancy, implying that humans have more degrees of freedom than necessary to perform a given task. As a consequence, humans have an infinite number of possibilities to do one task. Solutions used nowadays in motion simulation are mainly based on optimization trying to find a unique solution that satisfies a set of constraints while minimizing an objective function (see [1] for review). Nevertheless, some authors suggest that redundancy should be considered as an advantage rather than a problem to be solved. Indeed, Latash considers the human redundancy as an ability to adapt to the environment [2]. Moreover, studies showed that different ways to perform a task can coexist, questioning the pertinence of looking for a unique solution. Then, natural motion variability should also be simulated. Grasping and manipulating an object with the hand is one of the routine tasks of human beings and is frequently encountered in workplace evaluation and product design. In case of rotating a spherical object, a recent study showed a large variation in arm posture when grasping the object for a given rotation amplitude [3]. The work presented here aims at proposing a stochastic algorithm to predict the grasping posture as a function of the intended manipulation.

Methods: The rotation task consists in grasping and rotating a sphere. Rotation amplitudes range from -315° in counter-clockwise direction (CCW) to 270° in clockwise direction (CW). Actual subjects performed this task in order to compare our simulation results to real data.. Experimental results and details of the protocol have been published in [3].

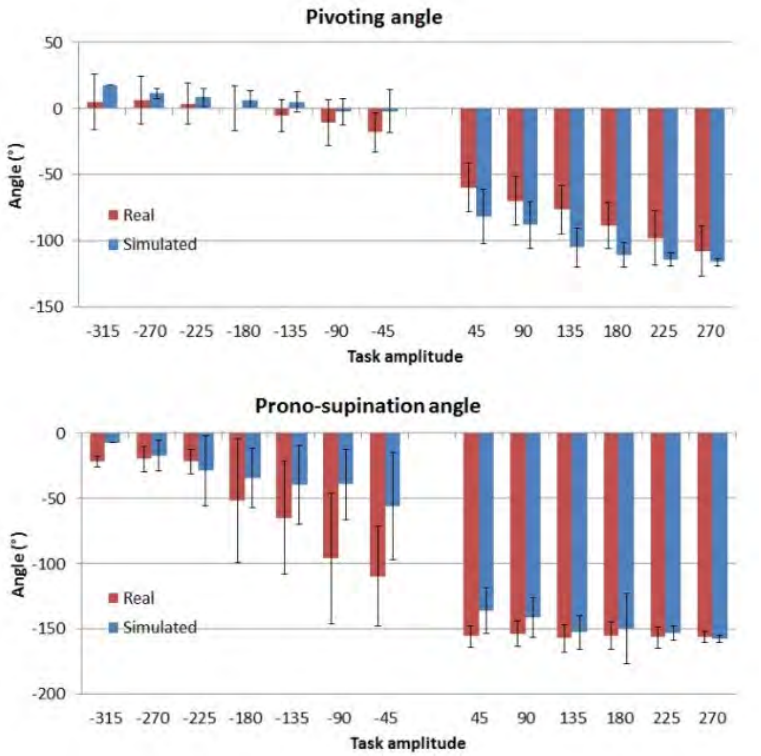
Hand palm is considered as a rigid plan formed by the head of the second metacarpal bone and the wrist styloids. Although there are multiple contact points between the palm and the sphere, we choose to limit our analysis to a unique contact point on the sphere, where the sphere and the palm share the same normal vector. From the shoulder to the palm, seven degrees of freedom are defined (3 for the shoulder, 2 for the elbow and 2 for the wrist).

Joint limits avoidance is based on Wang's work [4] which takes into account coupling effect of joint axes allowing us to have more natural simulated postures. Shoulder and wrist circumduction cones are based on data from the literature ([4] for the wrist and [6] for the shoulder), while axial limits of the upper arm are from [5].

The definition of the grasping posture is done as follow: 1- estimation of all the possible grasping points allowing an amplitude of rotation required by task; 2- a uniform probability distribution is attributed to these admissible points; 3- a grasping point is selected randomly; 4- the palm orientation around the selected grasping point is defined in order to maximize the shoulder-wrist pivoting angle margin at the beginning of the rotation, given the constraint that it must be inferior or equal to the pivoting margin at the end of the rotation; 4bis- if this constraint cannot be satisfied, another point is selected (step 3); 5- the elbow position is compute in the middle of the pivoting margin once the palm orientation is determined.

Results: Simulations were based on one subject's anthropometric data. Due to simulation constraints (rigid hand and no shoulder motion), we were only able to simulate grasping postures for the rotation amplitudes from -315° to 270°. Twenty simulations were performed for each amplitude. Figure represents the forearm (prono-supination) and shoulder-wrist (pivoting) angles for simulated and real postures. Globally, one can observe a similar evolution between the simulated and actual angles. Also, we have to note a tendency to have higher values for simulated pivoting angle in counter-clockwise rotations, i.e. a lower elbow position. Finally, as for the real data, simulated pivoting margins at the beginning and end of rotation show same behavior described in one of our previous work [3].

Figure:



Caption: Comparison of simulated and real arm angles

Conclusion: First conclusion of this work is the ability of our algorithm to simulate arm grasping postures in agreement with experimental data. Moreover, despite a quite simple probability distribution, simulations show interesting results in term motion of variability. Nevertheless this model could be improved taking into account individual joint limits. Finally, other probability distributions should also be tested.

COMPARISON OF MECHANICAL PARAMETERS OF TISSUE ENGINEERED AND NATIVE CARTILAGE: A NUMERICAL STUDY

Antonio Completo [1,*] Cátia Bandeiras [1] Antonio Ramos [1]

[1]Mechanical Engineering, University of Aveiro, Aveiro, Portugal

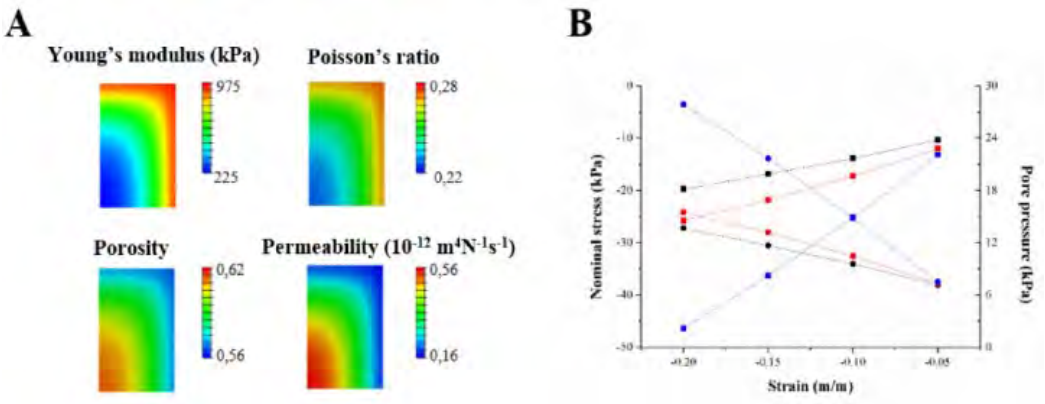
Introduction and Objectives: One of the main difficulties associated with tissue engineered cartilage is the unability, so far, to obtain tissues with homogeneous mechanical properties and similar to the native cartilage ones [1]. We will simulate the effects of biphasic mechanical properties obtained from simulation of free swelling culture of tissue engineered cartilage on the mechanical behaviour of the tissue in comparison to homogeneous tissue engineered cartilage and native cartilage with homogeneous mechanical properties.

Methods: Axisymmetric 2D slices of tissue engineered cartilage and native cartilage (2mm width x 2.34 mm height) were modelled in Abaqus v 6.12.1 (Dassault Systèmes, France). A biphasic model with isotropic neo-Hookean solid phase was implemented [2,3]. The mechanical properties of tissue engineered cartilage were calculated by replicating the experimental conditions in [1] and using the tool presented in [2]. The mechanical properties of the middle zone of articular cartilage were taken from [4]. Stress-strain compressive mechanical tests were simulated until 20% compression (0.05%/s) in all the samples.

Results: The distributions of the unloaded mechanical properties of tissue engineered cartilage are shown in Figure 1A. The average mechanical properties of tissue engineered cartilage are compared with the middle zone articular cartilage properties in Table 1. The nominal stress and pore pressure simulated for each case are shown in Figure 1B.

Table 1: Average mechanical properties of tissue engineered cartilage and native cartilage.

Figure:



Caption: Figure 1. A: Mechanical properties of tissue engineered cartilage obtained from simulation of the experimental conditions of [1] during 56 days. B: Average nominal stresses (squares) and pore pressures (circles) for heterogeneous TE cartilage (black), homogeneous TE cartilage (red) and native cartilage (blue).

Conclusion: The lack of nutrient supply to the cores of TE cartilage resulted in maximum/minimum relative differences of 23, 82, 90 e 29% for the Young's modulus, Poisson's ratio, porosity and permeability respectively. Heterogeneous TE cartilage has nominal stresses and pore pressures 23 and 12% inferior to the homogeneous TE cartilage and 57 and 51% inferior to the native cartilage. This is essentially due to the high average permeability of TE cartilage, approximately 6 times higher than the native cartilage one. Research on experimental procedures and materials that allow for a more optimal reduction of permeability and that allow to reduce the heterogeneity in the distribution of the parameters is important to obtain TE cartilage with mechanical behaviour more similar to the native cartilage one.

Table:

Property	TE cartilage	Native
E (kPa)	653.5	364
υ	0.205	0.24
ϕ	0.59	0.75
k (10^{-12} $m^4.N^{-1}.s^{-1}$)	0.0967	0.0172

CHEST MODEL FOR BLUNT AORTIC TRAUMA MODELLING CREATED USING MULTIPLE MODES OF IMAGING

Alan Parish [1,*] Francisco Carrasco-Hernandez [1] Donal McNally [1]

[1]Engineering, Nottingham University, Nottingham, United Kingdom

Introduction and Objectives: For finite element modelling of blunt aortic trauma in car crashes it is important to model not only the aorta but its surrounding tissues. As forces involved in the crashes interact with all the different tissues and are likewise affected by their varying mechanical properties.

To this end to ensure that the correct anatomical geometry of the tissues and the aorta was correct, multiple medical imaging models were used of a single cadaver taken from the visible human project [1].These data sets have the unique advantage that the subject was scanned in multiple modes post-mortem, (CT, MRI and photographically as the body was ground down). Also as the subject did not die from a heart related problem the aorta is in healthy condition.

The use of multiple data sets is important as segmenting out the body from a single data set such as CT is only feasible for dense tissues such as bone and not for soft tissue such as the heart, while the MRI data is good for soft tissue but not for dense. Therefore by combining the CT and MRI data as well as unique photographic data this data set also possesses, it is possible to build up a whole model of the chest area which would not be possible when using just a single data set.

This segmented model is advantageous over a simplified geometric model as it does not rely on assumptions about the shape and represents directly the relative position of all the different tissue types.

Methods: The three data sets were taken from a 38 year old male [1] and were all segmented using the software Mimics (Materialise) with the resultant 3D models being post processed in 3-Matic (Materialises). All the models were segmented directly, except for the aorta, which because of the thickness of its layers was constructed from the blood within it and then wrapped with layers of 0.27, 0.36 and 0.40mm to create a 3 layer model [2].

The different tissue contrast of the three data sets were used to create the model:

The bone, cartilage on the ribs, lungs and intestines were segmented from the CT data.

The heart was segmented from the MRI data.

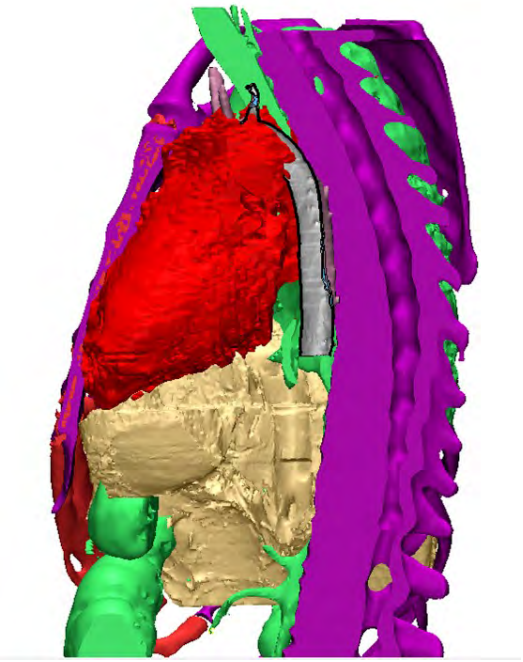
The aorta and liver were both segmented from the photographic data.

This combined imaging method provides the novel advantage of this model, namely as all the imaging data was collected post mortem all the tissue is stationary so unlike in a living subject the image data from all the different image sources can be over laid (on the photographic data set) to create a model which takes into account the different tissue types.

Once the different tissue types were segmented and meshed, the meshes were then cleaned and the number of elements reduced for the non-aorta meshes.

Results: The model created retains the anatomically determined geometry while having below 1.5 million elements, with the layers of the aorta possessing a higher proportion of the elements to size because they are the regions of interest.

Figure:



Caption: Cross section along the sagittal plane of the chest model, showing the complete heart and the layers in the aorta.

Conclusion: With the utilization of a unique post mortem data set and cutting edge segmentation software, it is possible to create a model for FEM which retains both the anatomically determined geometry as well as the segmenting out the different tissue types. Because of the different tissue's types properties, this would not be possible by using only a single data type such as CT, as such this multiply imaging types data set model allows for highly in-depth FEM to be performed in the future; which takes into account the actually shape and differing properties of the tissue types in the chest.

DEVELOPMENT OF A BILATERAL UPPER LIMB MUSCULOSKELETAL MODEL TO INVESTIGATE MUSCLE CONTRIBUTIONS DURING DIFFERENT PUSH-UP VARIATIONS.

Julie Ellis [1,*] James Johnston [2] Jon Farthing [1] Alison Oates [1] Joel Lanovaz [1]

[1]College of Kinesiology, [2]Dept. of Mechanical Engineering , University of Saskatchewan, Saskatoon, Canada

Introduction and Objectives: The ability to estimate upper limb muscle forces during dynamic tasks can improve understanding of bone and joint loading in both normal and pathological conditions. The push-up is a common and important exercise movement which provides dynamic loading to the arms. To date biomechanical analysis of push-ups have been limited to external force [1] and inverse dynamics analysis [2], and EMG based estimation of muscle activation [3]. Musculoskeletal models utilizing muscle-tendon representations allow estimations of muscle and joint contact forces but currently no published upper limb models have been applied to push-up loading tasks. The purpose of this study was to 1) develop a bilateral dynamic upper-limb musculoskeletal model capable of simulating loaded movements and 2) evaluate the model by simulating three push-up variations with different expected loading patterns.

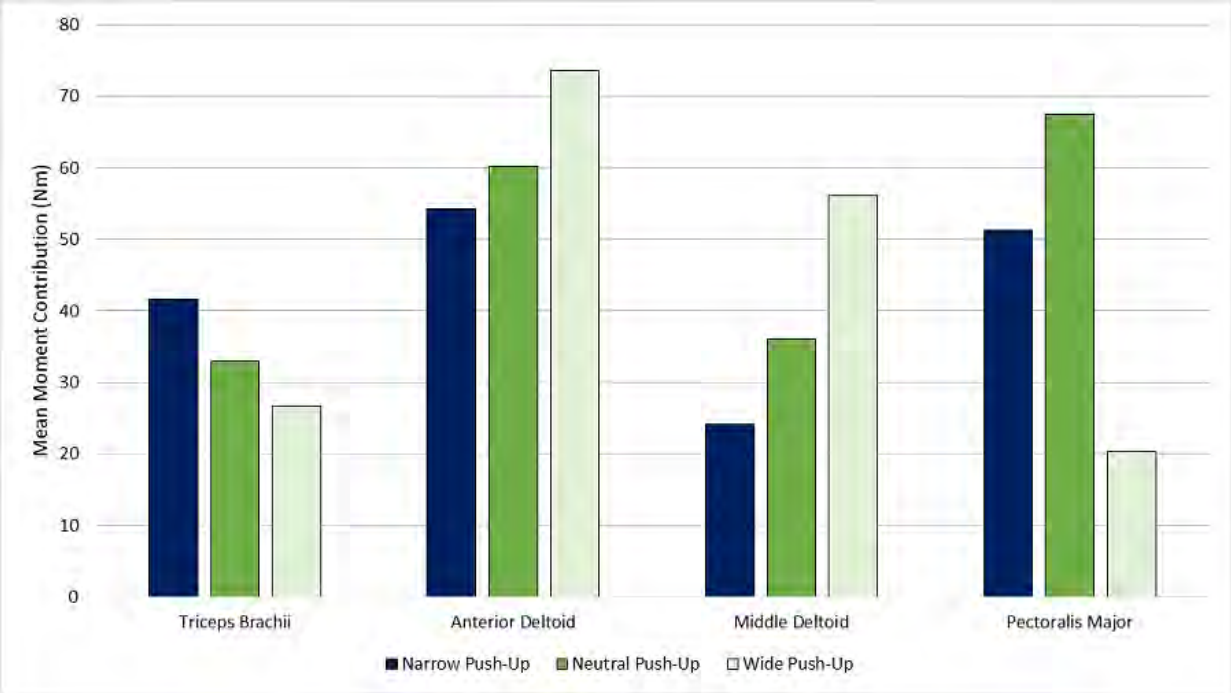
Methods: In this case study, a musculoskeletal model is used to estimate individual muscle contributions to net joint moments at the elbow and shoulder joints during push-ups with three different hand positions. A unilateral computational model of the upper limb [4], constructed in OpenSim [5], was adapted for this application. The original model was modified to include both arms which was required for simulating push-up movements and included 12 degrees of freedom (DOF) in each arm representing the sternoclavicular (SC), acromioclavicular (AC), glenohumeral, elbow and wrist joints. Movement of the SC and AC joints were constrained as a function of shoulder elevation based on de Groot & Brand [6]. Muscle moment arms from the original model [4] were maintained. A lower limb model was also included with 10 DOF representing the back, hips, knees, ankle, subtalar and metatarsophalangeal joints. The resulting bilateral whole body model included 100 Hill-type muscle representations in the upper extremities and ideal torque actuators controlling torso and lower extremity DOF.

Experimental data driving the analysis were obtained from a single male participant performing push-ups with three different hand widths (wide, neutral and narrow) and similar shoulder positions. Using a metronome, the timing of the push-ups were controlled at 0.5Hz. Kinematics of each variation were recorded using a 54-marker set with a three-dimensional motion analysis system (VICON, Denver, CO). External loads were measured by three force platforms, one under each hand (AMTI, Watertown, MA) with a third under both feet (Bertec, Columbus, OH). The OpenSim modelling platform [5] was used for analysis. The model was scaled and inverse kinematics and dynamics were performed. Single representative trials from each variation were selected for static optimization analysis to estimate individual muscle force contributions to the recorded movements. The estimated muscle forces and moment arms from static optimization were used to calculate moment contributions throughout the push-up movements. Muscle moments were averaged across the push-up cycle to calculate mean muscle moment contributions for comparison between hand position variations.

Results: Experimental net joint moments at the elbow were comparable to previously published data [2]. Simulations found the triceps brachii (elbow), anterior and middle deltoids and pectoralis major (shoulder) muscles to be the major

contributors during the push-up (Figure 1). Triceps were most active in the narrow hand position and least active in the wide position. Both anterior and middle deltoids followed an opposite pattern being most active in the wide hand position and least active in the narrow position. The anterior deltoids were always dominant over the middle deltoids. Pectoralis major produced the highest mean moment in the neutral hand position, followed by the narrow and wide positions. The patterns of individual muscle moment contributions between the three hand positions agreed well with previous EMG based estimations of muscle activation during similar push-ups [3].

Figure:



Caption: Figure 1: Mean muscle moment contributions to push-ups with narrow, neutral and wide hand positions.

Conclusion: The current study demonstrates an application of a novel bilateral upper extremity musculoskeletal model, simulating a relatively complex whole body dynamic task with external loading. Future work will include a range of participants and a sensitivity analysis investigating the effect of model parameter variation on outputs.

RELATING FEMORAL CONDYLE GEOMETRY TO ANTERIOR CRUCIATE LIGAMENT LENGTH

Melissa A. Boswell [1] Brian Davis [1,*] Michael Kelly [2] Danielle Filipkowski [2] John Elias [2]

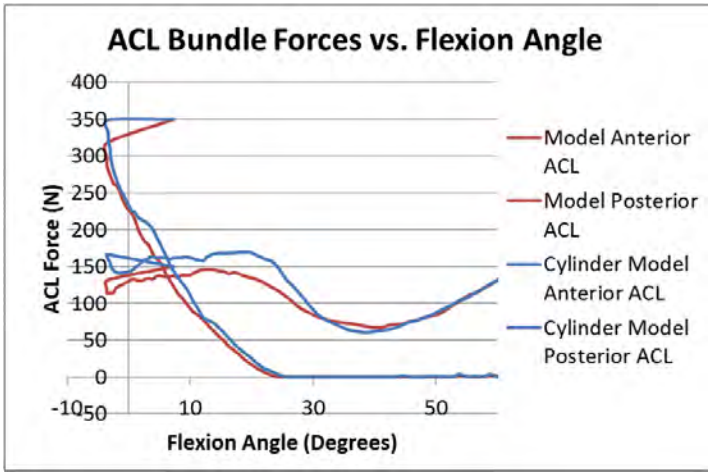
[1]Biomedical Engineering, The Univeristy of Akron, [2]Akron General Medical Center, Akron, United States

Introduction and Objectives: A relationship between femoral condyle geometry and ACL length, although not currently quantified, would facilitate optimal knee reconstructive surgery. In this study, the relationships between the radii of the femoral lateral and medial condyles and the length of the ACL bundles were evaluated using knee computational models.

Methods: Ligaments and muscles were modeled as described previously [1], with the models used to simulate dynamic knee flexion with eccentric muscle contractions. The anterior and posterior ACL bundle lengths were measured from tibial to femoral insertion points. For each condyle, anterior and posterior cylinders were used to represent the distal femoral anatomy. The models were run with the contact between the femur, or cylinders, and the tibia guiding the motion. ACL force vs. flexion angle of the tibia for the two contact conditions was compared to confirm that the radii of the fitted cylinders matched those of the patients' knees.

Results: In one knee model, both the tibiofemoral contact model and cylinder contact model had an ACL posterior bundle force starting at 350N and steadily decreased to 0N at 25° flexion and an ACL anterior bundle starting at 150N and reaching 80N at 50° flexion. A similar pattern for the other knees indicates that the radii of the cylinders fitted matched that of the condyles and the radii length could then be compared to the ACL bundle lengths.

Figure:



Caption: A similar pattern in ACL bundle forces before and after the cylinders were fitted to the model indicates that the cylinders closely resemble the femoral condyle geometry.

Conclusion: The results supported the hypothesis that there is a close synergy between condyle geometry and ACL length.

PO-0229

SIT-TO-STAND PREDICTION FOR A RIGID LINK HUMAN MODEL

Valerie Norman-Gerum [1,*] John McPhee [1]

[1]Systems Desgin Engineering, University of Waterloo, Waterloo, Canada

Introduction and Objectives: Decreased capacity to perform sit-to-stand (STS), often due to effects of aging, disease, or injury, limits patient mobility and independence. Available interventions are evaluated based on past outcomes and performance in the clinic. A better option is to first assess interventions in silico, by creating computational patient and intervention models to support predictive simulation of motion.

A model of a healthy patient was created from the literature and experiments. Its motion is driven by Bézier curves, optimized to minimize joint torques. The predicted motion is evaluated against normative events of STS. This work will be used as a foundation for predictive simulation with models and performance criteria more closely tied to human physiology, including muscle dynamics, for greater fidelity in motion prediction.

Methods: A biomechanical model was constructed in MapleSim (Maplesoft, Canada) to represent a typical adult Caucasian female (61.9kg, 1.735m) (Fig.). The model's three links, HAT (head, arms, and torso), thigh, and leg, are connected by two planar revolute joints at the hip and knee, and to the ground by a revolute joint at the ankle. Thus, the model moves in the sagittal plane only. Forces between the chair and seat of the patient were modelled using a nonlinear spring-damper and hyperbolic tangent Coulomb friction. The parameters of this model are taken from the literature [1, 2] as well as from experiments.

Sit-to-stand dynamics and kinematics of one subject were measured using AccuGait force plates (Advanced Mechanical Technology, USA) and MVN Biomech motion capture system (Xsens, Netherlands). Seat contact parameters were estimated using an optimization routine executed in MATLAB (The MathWorks, USA), which minimizes the difference between measured ground reaction forces and those calculated when driving the model with measured kinematics. The kinematics also provided the orientation of body segments used to calculate the inertial parameters of the HAT.

The model was then simulated independently of experimental data. The hip angle and vertical and horizontal locations of the hip were modelled as Bézier curves, with the first and last knots constrained to describe static sitting and standing poses, respectively. The locations of these knots were optimized to minimize the sum of squared joint torques required for the model to achieve STS. The number of knots was increased sequentially until the solutions converged to an optimal motion.

Dynamics and kinematics of the patient model were calculated for the predicted STS. From these, the markers of STS events [3] were calculated as a percent of the total time taken to complete the motion and compared to normative data.

Results: Sit-to-stand as predicted for the human model is presented in the Figure and Table. The six phases of the STS cycle, quiet sitting, initiation, seat unloading, ascending, stabilization, and quiet standing [3], are present in the prediction. The events defining the phases are in proper sequence. The spacing of the events is uncharacteristic when examined in context of the statistics in the Table. Predicted vertical acceleration begins early and terminates late, seat off is early, and the stabilization phase is short. The predicted motion is analogous to STS; however it is not typical.

Figure:

Caption: A photo of the experiment behind a series of images of the model performing the predicted STS.

Conclusion: Predictive simulation of human motion requires a model that appropriately represents the human body with a physiologically representative optimal control formulation. The rigid link model created is clearly not a human and the cost function used, minimizing a function of joint torques, is abstract; however the predicted STS resembles that of a human. This model will soon be supplemented with models of muscles; this step toward biofidelity will provide the context to enforce achievable joint torques and specify more physiological performance criteria including functions of muscle forces and joint contact forces.

The current model has been used to predict STS with the normative sequence of phases and events. The objective of future modelling is to predict event occurrence within the range of event times in the healthy human population.

Table:

	Event					
	Initiation	Start of vertical acceleration	Seat off	End of vertical acceleration	Start of stabilization	Standing on
Prediction	0.0	1.4	21.3	76.9	97.2	100.0
Average	0.0	26.5	33.2	45.3	72.7	100.0
Standard Deviation	0.0	6.1	5.7	5.3	4.1	0.0
Minimum	0.0	41.2	47.1	56.1	82.2	100.0
Maximum	0.0	18.3	25.7	35.9	66.3	100.0

KINEMATICS AND DYNAMICS OF FOUR R-TYPE JOINT ANTHROPOMORPHIC FINGER

Anil Kumar Gillawat [1] Hemant J Nagarsheth [1,*] Mansi H. Nagarsheth [2] Nirmal Kumar Kushwaha [3]

[1]Department of Mechanical Engineering, Sardar Vallabhbhai National Institute of Technology, [2]Department of Physiology, Surat Municipal Instiute of Medical Education & Research, Surat, [3]Department of Mechanical Engineering, Babaria Institute of Technology, Vadodara, India

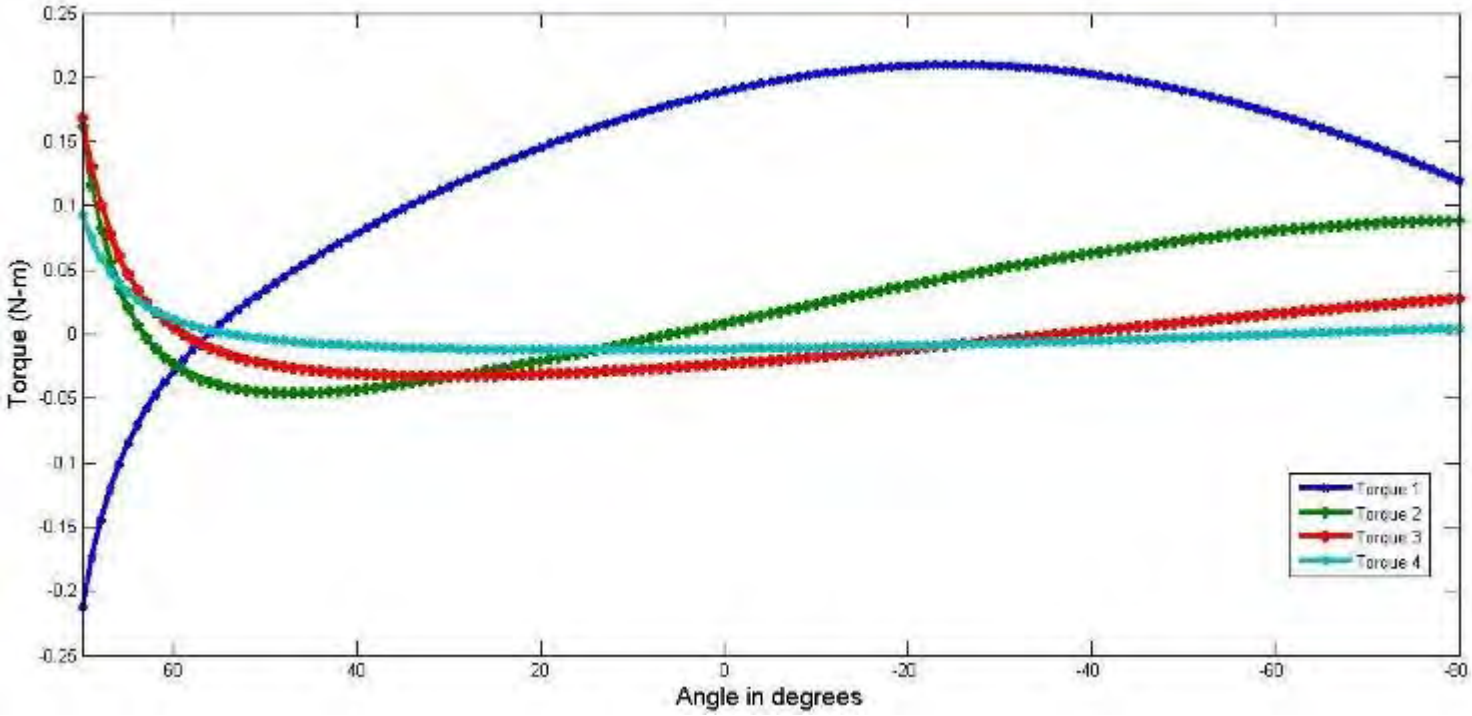
Introduction and Objectives: Kinematic and Dynamic analysis of human hand, end effectors, desired trajectory and output power has derived the interest of many researchers in the field of designing [Fukui et al], analysis [Butz et al] and modeling [Yamane et al.] of anthropomorphic fingers. This paper presents the study of kinematics and dynamic analysis of an anthropomorphic finger with four revolute joints (R- joints). The torques are derived and plotted against the angle of rotations. The results are analyzed and justified. Kinematic Analysis is used to find out the position, velocity and accelerations without considering the forces causing the motion. Denavit-Hartenberg table (D-H Table) is generally used for kinematic analysis. Dynamic equation is used to derive the torques and forces which are used as inputs for designing the controllers. Two formulations: Newton-Euler formulation and Lagrange-Euler formulation are used to derive the dynamic equations. In this paper, Lagrange Euler formulation is used for deriving the torque equations.

Methods: Kinematic Analysis of finger joints is carried out in order to find the position, velocity and acceleration, which are used as inputs to the dynamic equations. The Dynamic equations are derived to find out the torques and forces which are again useful in designing controllers. D-H table is used for kinematic analysis and Lagrange-Euler formulation is used to derive the dynamics equations. MATLAB is used for obtaining the torque results which are used to depict the relation between the rotated angle and the torque encountered for both lifting conditions (with and without load). The Dynamic analysis is carried out at all the joints of finger considering flexion only. All the joints: Metacarpophalangeal joint (MCP), Proximal interphalangeal joint (PIP) and Distal interphalangeal joint (DIP) are assumed to be revolute and able to produce flexion and extension motion of the fingers only.

Results: The torque results are obtained from the dynamic equations and graphs for Torque vs Angle are plotted for both the cases: (i) no load condition and (ii) lifting load of 50 gm having diameter of 50 mm. For the particular case, all motors are assumed to be in unconstrained motion. remaining motors are assumed to keep the links stationary, which requires some torque at these joints. The rotation of one joint had some effect on the other joint on the same finger, which is depicted in the figures. Joint torque behaviour is studied for unconstrained rotation of joints. When all joints are rotating with no load, DIP joint has minimum torque and maximum torque for CMC joint. All joint torques have depicted same behaviour within the restricted range of motions. Figure 1 shows that the maximum torque is required at the starting as it has to overcome the static forces. The torque reduces drastically and then adopts the sinusoidal behaviour, with peak value less than the starting torque. The maximum torque is experienced by CMC joint as it has to sustain the load of the complete finger as depicted by kinematic model. The maximum torque is experienced by CMC joint, which is responsible for lifting of complete finger and is minimum for DIP joint, which is responsible for lifting only last link (Distal Phalange). CMC joint torque has to balance the remaining joint torques and hence rapid increase in joint torque is observed. CMC

joint has negative starting torque which is different from the remaining joint torques. Starting torque for theMCP, PIP and DIP joints is found to be maximum and reduces drastically and then adopts the sinusoidal behaviour, which has peak value less than the starting torque. All the four joint torques exhibit the sinusoidal behaviour. The negative joint torque suggests that resisting torque is greater than the applied torque for lifting other links and payload attached to the joint torques and acts against the gravity to keep the links stable. Initial high positive torque obtained indicates that obtained torque is positive and the resisting force is zero.

Figure:



Conclusion: Mathematical modeling for joint torques are derived using D-H approach and Lagrange-Euler approach. The torque results are obtained by using MATLAB and the relations are depicted. The results are found to be satisfactory. The results can be useful for physical therapy and rehabilitation of hand with minimum load on the joints. The effect of rotation of one finger on other can be considered for further study.

EFFECTS OF SURGICAL BREAST CANCER TREATMENT ON THREE-DIMENSIONAL SCAPULAR KINEMATICS DURING UPPER-LIMB MOVEMENT

Ivana Ribeiro [1,*] Paula Camargo [1] Angelica Ferrari [1] Maíra Lixandrão [1] Tania Salvini [1]

[1] Departament of Physical Therapy, Universidade Federal de São Carlos, São Carlos, Brazil

Introduction and Objectives: The residual effects of surgery treatment for breast cancer may affect upper limb function, strength and movement. Patients report shoulder pain, weakness, tightness and reduced functional capacity. Limited shoulder motion and function are consistently identified following surgical breast cancer treatment and subsequent both axillary lymph node dissection and sentinel node biopsy. These procedures can decrease functional activities, particularly overhead reaching and quality of life in breast cancer survivors. Normal scapular motion during arm elevation consists of upward rotation, posterior tilt and external rotation. In breast cancer survivors, altered motion patterns can be presented in the affected side. However, it is not known yet if the type of surgery procedure associated to axillary lymph node dissection can contribute to abnormal scapular movement. Therefore, the purpose of this study was to assess the scapular kinematics in women who had undergone a surgical breast cancer treatment.

Methods: Seven women who had surgical breast cancer treatment were evaluated (42.8± 5.6 years; 72.2±18.3 kg; 1.64±0.01m; Disabilities of arm, shoulder and hand questionnaire: 36.3±29.6). Most of them had undergone mastectomy surgery (5 participants) than quadrantectomy procedure (3 participants) both associated to axillary lymph node dissection.The period of surgery was closer to 2 years (mean: 24.7±16.8 months) and all participants had taken chemotherapy after surgery in the non-affected side. The Flock of Birds® electromagnetic tracking system was used to evaluate scapular kinematics during elevation and depression of the arm in the scapular plane. Local coordinate systems were established for the trunk, scapula, and humerus using the digitized landmarks following the protocol recommended by the International Society of Biomechanics (Wu et al., 2005). Three repetitions were recorded with the individual in the standing position. Kinematic motion analysis involved selecting scapular data at 30°, 60° and 90° of arm elevation. The results were analyzed using the SPSS statistical package. A two-way ANOVA was used to identify angle x group interaction or main effect of group. The level of significance was considered 5%.

Results: For scapular internal rotation, the interaction side × angle was not significant as well as main effect of group for elevation ($p=0.75$, $p= 0.93$, respectively) and lowering ($p=0.31$, $p= 0.95$, respectively) of the arm. For scapular upward rotation, the interaction side × angle was not significant as well as main effect of group for elevation ($p=0.79$, $p= 0.76$, respectively) and lowering ($p=0.10$, $p= 0.55$, respectively) of the arm. For scapular tilt, the interaction side × angle was not significant as well as main effect of group for elevation ($p=0.22$, $p= 0.34$, respectively) and lowering ($p=0.13$, $p=0.58$, respectively) of the arm. The mean difference between sides was 0.37° ± 4.31°, 1.21° ± 3.93° and 2.18° ± 2.21° for scapular internal rotation, upward rotation and tilt, respectively, during arm elevation. For lowering of the arm, the mean difference between sides was 0.21° ± 3.66°, 2.55° ± 4.17° and 1.32° ± 2.34° for scapular internal rotation, upward rotation and tilt, respectively, during arm elevation. The absence of altered scapular kinematics may represent compensatory responses for scapular function improvement during arm elevation. In fact this is according to Shamley and colleagues

(2012) who concluded that shoulder morbidity after surgical breast cancer treatment is bilateral. In addition, this could be related to chemotherapy exposure in the non-affected side after surgical treatment.

Conclusion: Scapular kinematics during elevation of the arm do not differ between affected and non-affected sides in woman who had undergone surgical breast cancer treatment. Besides, it is important to consider the small sample size in this study. Futures studies are needed, especially with a large sample size to verify possible alterations in scapular kinematics.

COMPARISON OF KNEE JOINT KINEMATICS AND KINETICS BETWEEN ANTERIOR CRUCIATE LIGAMENT DEFICIENT AND HEALTHY SUBJECTS DURING RUNNING

Saud M. Alarifi [1,*] Lee Herrington [1] Richard Jones [1]

[1] Knee Biomechanics and Injury Research Programme, University of Salford, Salford, United Kingdom

Introduction and Objectives: Anterior cruciate ligament (ACL) and patellofemoral joint (PFJ) injuries are common and cause significant time loss to sports participation, as well as the reported increased risk of osteoarthritis (OA) from ACL and PFJ injuries. There is little data on why individuals with an ACL-deficient (ACL-D) or ACL-reconstructed knee consequently develop OA but altered kinematics and kinetics are one of the hypothesised reasons. Numerous studies investigating walking gait have found significant reductions in knee flexion moment and small reductions in peak knee flexion angle, with individuals adopting a quadriceps avoidance gait pattern during walking. One of the most common activities pre- and post-surgery is running and it is not known if individuals with an ACL-D knee have different knee kinematic and kinetic patterns to healthy runners. In the absence of typical function of the ACL, the ACL-D individuals may subconsciously avoid contraction of the quadriceps to avoid displacing the tibia anteriorly during jogging where dynamic loads are greater. This may then increase the risk of development of generative diseases due to excess loading so understanding if there are differences is of utmost importance. Therefore, the purpose of this study was to compare the knee kinematics and kinetics between a group of ACL deficient individuals and healthy non-injured subjects during running. We hypothesised that the ACL-D individuals would have differences in knee kinematics and kinetics compared to the non-injured healthy group.

Methods: Eight individuals (2 female, mean +/- standard deviation age, height and mass are 22.5 ± 4.72 years, 1.73 ± 0.08 m, 74 ± 16.4 kg) who had sustained an ACL injury and were on the waiting list for reconstruction were recruited to the study, were compared with Eight healthy subjects (6 males, 29.2±4.89 years; mean height, 1.69±0.03m; mean mass, 68.4±8.39Kg). Each participant underwent a single assessment. A twelve-camera Qualisys motion analysis system (240 Hz), with an AMTI force platform (1200 Hz) embedded in the running track floor, was used to collect the kinematic and kinetic data.

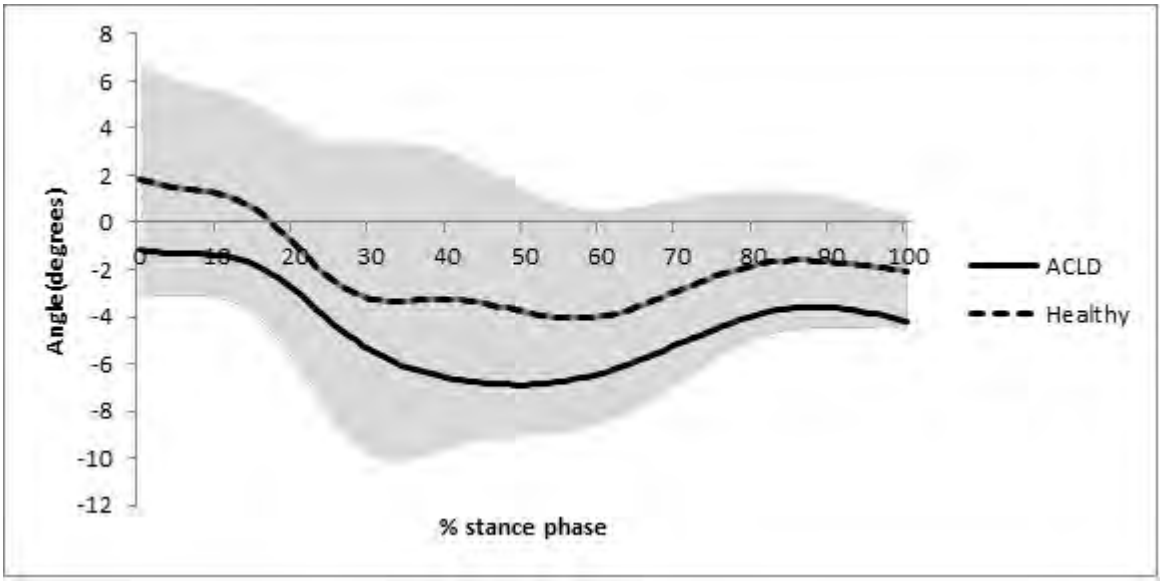
Subjects ran along a twenty two metre runway at a self-selected speed, which was recorded with timing gates. Each subject performed five successful trials. The contact phase (initial contact to toe off) of five trials was normalised to 100% of stance and averaged for each condition.

Data were post-processed with Visual 3D software (C-motion Inc. USA) where the marker trajectory data were filtered at 12 Hz, and force data were filtered at 25 Hz using a fourth-order Butterworth low-pass filter. Euler angles to calculate three-dimensional angular motions between segments, and joint kinetics were calculated using a six-degree of freedom, inverse dynamics model. The outcome variables included peak knee valgus angle, peak knee flexion angle during early stance (first 30%), peak sagittal and coronal moments and peak vertical ground reaction force at stance phase.

Statistical analysis was performed with SPSS Version 22.0 (IBM SPSS, Chicago, IL), using a t-test to compare between ACL-deficient injured patients and the healthy subjects at the 95% confidence interval ($p<0.05$).

Results: The running speeds were not significantly different between the two groups ACL-D 3.28±0.13 m/s, non-injured 3.02±0.29 m/s ($p > 0.05$). For the knee kinematics and kinetics, none of the outcome variables were significantly different to one another during the running activity ($P > 0.05$).

Figure:



Caption: Figure 1: Knee valgus angle (-) during running for the ACL-D and healthy subjects (mean ± standard deviation).

Conclusion: This study showed no significant differences in knee kinematic and kinetic variables during running between the ACL deficient and healthy non-injured subjects. It would appear that ACL deficiency does not have a significant effect on the knee in how an individual runs in a straight line pre-ACL reconstruction. Further investigation is warranted to determine if these variables differ once reconstruction has occurred, as this may impact on the aetiology of degenerate joint disease found commonly post surgery.

Table:

Events	Peaks at stance phase			Peaks at early stance

PO-0234

DIFFERENTIATION CAPABILITY OF DYNAMIC AND STATIC KINEMATIC MEASUREMENTS OF REARFOOT EVERSION IN PATELLOFEMORAL PAIN

Danilo Silva [1,*]Ronaldo Briani [1]Marcella Pazzinatto [1]Deisi Ferrari [2]Fernando Aragão [3]Carlos Albuquerque [3]Fábio Azevedo [1]

[1]Physiotherapy, University of São Paulo State, School of Science and Technology, Presidente Prudente, [2]Bioengineering, University of São Paulo, São Carlos, [3]Physiotherapy, State University of West Parana, Cascavel, Brazil

Introduction and Objectives: One of the most common knee disorders affecting young individuals is Patellofemoral Pain (PFP)[1]. Excessive rearfoot eversion is thought to be a risk factor for patellofemoral pain development, due to the kinesiological relationship with ascendant adaptations. Individuals with PFP are often diagnosed through static clinical tests[1], however, the adaptations seem to appear in dynamic conditions. Thus, the aim of this study was to determine the differentiation capability of three rearfoot eversion measures: rearfoot range of motion, static clinical test and static measurement using a 3D system.

Methods: 29 individuals with PFP and 25 control individuals (18–30 years) participated in this study. Motion analysis was collected using a three-dimensional motion-analysis system (VICON MX, Vicon Motion Systems Inc.; Denver–EUA) combined with 4 cameras (type Bonita®B10) operating at a sampling frequency of 100 Hz with a resolution of 1 megapixel. Ground reaction forces were collected using a force plate (AMTI, OR6, Watertown, USA) at a sampling frequency of 200Hz. To perform kinematic evaluation of each participant during stair climbing the Oxford Foot Model was used associated with a plug-in gait model to perform static calibration. A static trial was collected to verify the rearfoot eversion angle measured by the system. Each trial was filtered with a fourth-order Butterworth low pass filter with a cut-off frequency of 6 Hz. The retro reflective markers were identified and labeled within the Vicon Nexus® 1.8 for reconstruction. Gait events (heel strike and toe off) were identified using the force plate data. In addition, one rater has performed a rearfoot static clinical test, which is a classical measure in PFP evaluation. Receiver operating characteristic (ROC) curves were done to show the differentiation capability (diagnostic accuracy) of each variable.

Results: In the sequence, the results of specificity and sensitivity for the optimal cut off and area under the curve values (Table 1). Regarding area under the curve, the rearfoot range of motion was classified as moderately accurate (0.71), whereas the static variables were classified as less accurate (0.63; 0.60), in addition, the only dynamic variable showed the best combination of sensitivity and specificity values at 72% and 63%, respectively. Despite growing evidence that excessive rearfoot eversion is one of the PFP etiological factors, instruments used to enable this evaluation are not well-established. Foot posture has been frequently evaluated in individuals with PFP under the assumption that measuring static structure will provide insight into the dynamic function, although this is unproven[2]. Comparing static measures, the best was rearfoot eversion measured by a 3D system, however, Area under the curve = 0.63, Sensitivity = 59% and Specificity = 59% values do not characterize this variable as a confident differentiation tool.

Conclusion: This study provides some evidence on the behavior of rearfoot eversion kinematics theoretically associated with PFP. Therefore, rearfoot range of motion alterations are not seen in static measurements which could be a reasonable explanation for the lack of success of orthotic treatment. The rearfoot range of motion during stair climbing

variable presented the best results in terms of differentiation capability. Static variables seem not to be related to individuals with PFP, due to low accuracy values. Therefore, the results were not better than other biomechanical variables in the literature, questioning the importance of distal factors in PFP.

Table:

Variable	Sensitivity %	Specificity %	Area Under the Curve (95%CI)	Standard Error	P-value
REROM	72	63	0.71 (0.55 – 0.86)	0.078	0.014
RESM	59	59	0.63 (0.47 – 0.80)	0.082	0.106
Clinical Rater	63	45	0.60 (0.42 – 0.78)	0.091	0.091

PO-0235

CRITICAL FLUCTUATIONS OF POSTURAL STABILITY AS A FUNCTION OF OSCILLATORY PLATFORM MOVEMENT

Aviroop Dutt-Mazumder [1,*] Karl M Newell [2]

[1]Kinesiology, The Pennsylvania State Uiversity, State College, [2]Kinesiology, The University of Georgia, Athens, United States

Introduction and Objectives: Addressing self-organization coordination processes involved while standing on an oscillatory platform is one avenue that reflects the emerging behavior of phase transition at the critical fluctuating point with respect to higher oscillating frequencies. Such experimental setup gives an insight to investigate the degenerate ways of maintaining stability despite encompassing the numerous degrees of freedom of the movement system in action[1]. In a simple rhythmic movement the fundamental elastic and frictional functions limit the ways in which the body's multiple subset can be assembled into a comprehensive rhythmic unit of few degrees of freedom[2].

We investigate how the postural system regulates the joint space degrees of freedom when subjected to lateral oscillating perturbation through the lens of phase portraits and relative phase. The aim was to investigate the coordination changes of a ML stance on a moving platform. It was hypothesized that center of mass(CoM)-center of pressure(CoP) and Head-CoP would abruptly shift from in-phase (low platform frequencies) to anti-phase (higher frequencies)[3].

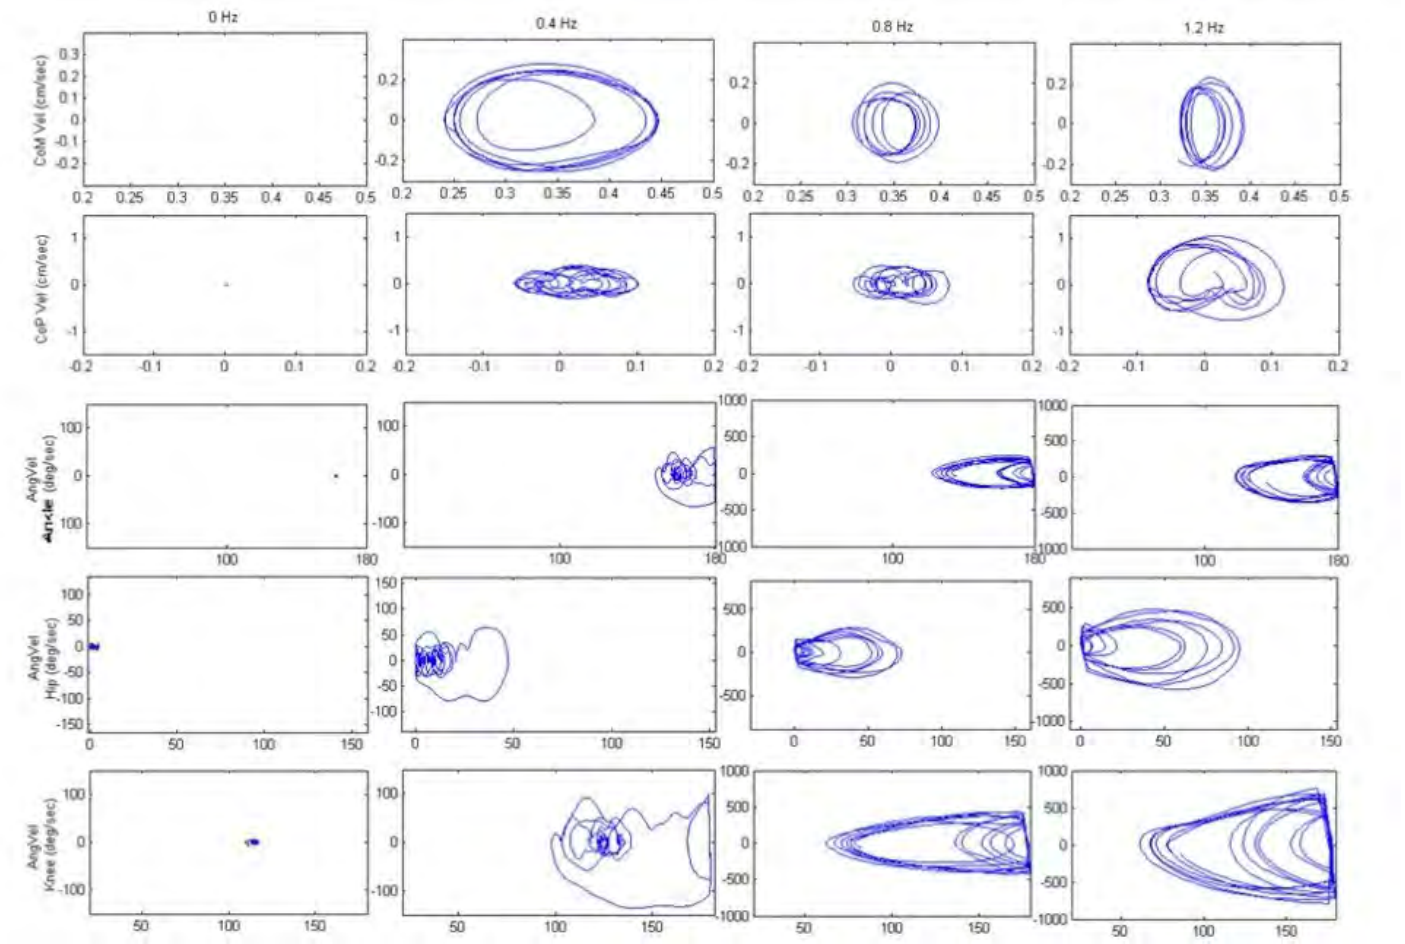
Methods: Twelve healthy male participants were recruited, according to the experimental protocol approved by Pennsylvania State University IRB.3-D motion analysis system (QTM, Sweden) was enabled to record 13-segment model reconstructed from an 18-marker system[3]. A force platform (AMTI, OR 6-5-1000) was used to derive the displacement of the CoP and was mounted on a moving platform that translated sinusoidally in the M-L direction. The participant were instructed to maintain their postural balance when they stood on the moving platform with bare feet placed side-by-side comfortably and kept their arms folded across their chest. The moving platform was controlled by a motor that generated oscillated at six frequencies (0.2, 0.4, 0.6, 0.8, 1.0 and1.2) Hz with a constant amplitude of 20 cm. Each day had a six trial block that had 1 min of intra-trial recovery.

Results: Fig.1 presents the phase portraits of the joint angular trajectories[4]. Qualitatively inferred, that there is a definite frequency and amplitude relationship with the oscillating platform frequency. Lower frequency (e.g. 0.2 Hz) all the lower limb joints (ankle, knee and hip) exhibits overlapping phase plane trajectories, indicating small amplitude but higher frequency and large variability in the joint angular motions. However, the joint motions exhibit a different shape of phase plane trajectories with increasing oscillating frequency of the moving platform. Between 0.4 Hz-0.6 Hz which is our predicted phase transition frequency band, we can see that the oscillations being unwrapped and moving towards larger amplitude, hence there is significant amount of less overlapped trajectories in the joint space giving rise to smoother limit cycles. The knee angular motion has less angular space exploration than ankle or hip joint across both feet as a function of increasing oscillating platform frequency.

CoM-CoP coupling moves from in-phase (36º) to anti-phase (142º) (Table 1). The SD peaks at 0.4 Hz (which is the phase transition frequency) and decreases as the frequency is increased further. This could reflect that the coordination of CoM-CoP is undergoing large instability during the phase transition region. CoM-Platform and CoM-Head remain largely

unchanged and stays in-phase irrespective of the increasing frequency conditions. The Head-CoP coupling shows a similar trend that of CoM-CoP, which is a shift from in-phase mode to an anti-phase mode after undergoing a phase transition at 0.4 Hz. The joint angular coupling of at the local level (Hip-Knee and Knee-Ankle) reflect that there is a gradual increase to anti-phase mode during 0.6-0.8 Hz before retreating back to in-phase mode. In other words, the local joint synergies are strongly coupled at a lower and higher frequency in order to maintain stability whereas they are loosely coupled (large M and high SD) during the unstable region of the phase transition period in order to accommodate postural balance.

Figure:



Caption: Phase portrait of global (x-axis: cm, y-axis: cm/sec) and local variables (x-axis: deg, y-axis: deg/sec)

Conclusion: CoM-CoP was considered as a candidate of collective variable of multi-segmental whole body postural system based on coordination dynamics perspective[2] we extend such proposition further by suggesting Head-CoP to be an alternative control variable candidate as well.

Table:

Frequency	Mean & SD	CoM-CoP	CoM-Plat	CoM-Head	Head-CoP	Head-Plat	Hip-Knee	Knee-Ankle
0.2 Hz	M	36	3	2	39	5	1	1
	SD	37	6	4	27	8	9	8
0.4 Hz	M	142	10	2	157	12	2	4
	SD	54	6	7	56	13	15	3
0.6 Hz	M	153	5	3	159	2	96	98
	SD	34	6	4	48	8	79	91
0.8 Hz	M	107	16	12	108	40	176	101
	SD	25	10	38	63	53	43	135
1.0 Hz	M	132	27	14	153	167	96	95
	SD	19	10	40	63	111	35	68

STRENGTH AND SCAPULAR KINEMATICS IN ASYMPTOMATIC NON-THROWERS WITH AND WITHOUT POSTERIOR CAPSULE TIGHTNESS

Dayana P. Rosa [1,*] Paula Camargo [1] John Borstad [2]

[1]Physicaltherapy, UFSCar, São Carlos, Brazil, [2]Physicaltherapy, Ohio State University, Columbus, United States

Introduction and Objectives: Posterior capsule of the shoulder is an important restraint during movements of the upper limb mainly when horizontal adduction is associated to internal rotation. Studies have indicated that posterior capsule tightness can be related to deficit in strength of the external rotators of the shoulder and alterations in scapular kinematics in overhead athletes, especially throwers. It was described that high stress loads are transferred to posterior capsule in the deceleration phase of the arm during the throwing motion, which can lead to tightness of this structure. However, it is not known yet if same alterations are present in a general population of non-throwers. Therefore, the purpose of this study was to assess the strength of the shoulder external rotators and scapular kinematics in asymptomatic non-throwers with and without posterior capsule tightness.

Methods: Sixteen individuals with no shoulder pain were evaluated and divided in 2 groups: with posterior capsule tightness (6 women and 1 man; 26.28 ± 2.69 years; 59.42 ± 7.39 kg; 1.63 ± 0.09 m) and without posterior capsule tightness (7 women and 2 men; 25.66 ± 3.08 years; 64.05 ± 10.77 kg; 1.67 ± 0.08 m). All of them were not involved to overhead sports. The posterior capsule tightness was determined by the low flexion test as described by Borstad and Dashottar (2011). This test was performed with the individuals in the standing position. They were passively positioned in 60° of arm elevation in the sagittal plane, and then the evaluator measured the bilateral internal rotation range of motion with a digital inclinometer aligned with the radial styloid. A difference of at least 7° in internal rotation between both arms was used to classify individuals with tightness. All individuals from the posterior capsule tightness group presented tightness in the dominant side. The group without posterior capsule tightness was paired to the side to be evaluated. Strength of the external rotators was measured unilaterally in the sitting position with a handheld dynamometer. Two repetitions were performed and the evaluator was blinded for measurements. The Flock of Birds® electromagnetic tracking system was used to evaluate scapular kinematics during elevation of the arm in the sagittal plane. Local coordinate systems were established for the trunk, scapula, and humerus using the digitized landmarks following the protocol recommended by the International Society of Biomechanics (Wu et al., 2005). Three repetitions were recorded with the individual in the standing position. Kinematic motion analysis involved selecting scapular data at rest, 30°, 60°, 90° and 120° of arm elevation. The results were analyzed using the SPSS statistical package. For external rotation strength, an independent t-test was used to identify differences between groups. For scapular data, a two-way ANOVA was used to identify angle x group interaction or main effect of group. The level of significance was considered 5%.

Results: The posterior capsule tightness group presented a difference of 9.11° ± 1.25° of internal rotation between sides while the group without posterior capsule tightness presented 3.11° ± 1.27°. No differences were detected in the strength of the shoulder external rotators (p=0.50) between groups (posterior capsule tightness: 1.31 ± 0.14 N/kg; no posterior tightness 1.35 ± 0.32 N/kg). The two-factor interaction of group x angle and the main effect of group were not significant

(p>0.05) for scapular internal rotation, upward rotation and tilt. The mean difference between groups was 1.73° ± 1.94°, 0.76° ± 2.96° and 0.69° ± 2.62° for scapular internal rotation, upward rotation and tilt, respectively. The lack of difference between groups in the present study can be due to the small sample size analyzed. The increased posterior muscle tension and humeral retroversion have also been described as possible contributors for posterior capsule tightness. The threshold of 7° to determine the tightness of the posterior capsule may not be ideal because it does not take into consideration the humeral retroversion. This difference between limbs may be different due to humeral retroversion instead of being a real tightness of the capsule. Although the low flexion test has not been validated in vivo yet, this test demonstrated greater tension of the posterior capsule in a cadaveric study compared to other tests (Borstad and Dahsottar 2011).

Conclusion: Strength of the shoulder external rotators and scapular kinematics during elevation of the arm do not differ between asymptomatic non-throwers with and without posterior capsule tightness.

INFLUENCE OF FATIGUE ON THE VARIABILITY OF THE GROUND REACTION FORCES DURING A PROLONGED RUNNING ON AN INSTRUMENTED TREADMILL

Sang-Kyoon Park [1] Sihyun Yoo [2] Hea Lee Park [2] Ji-Seon Ryu [3,*]

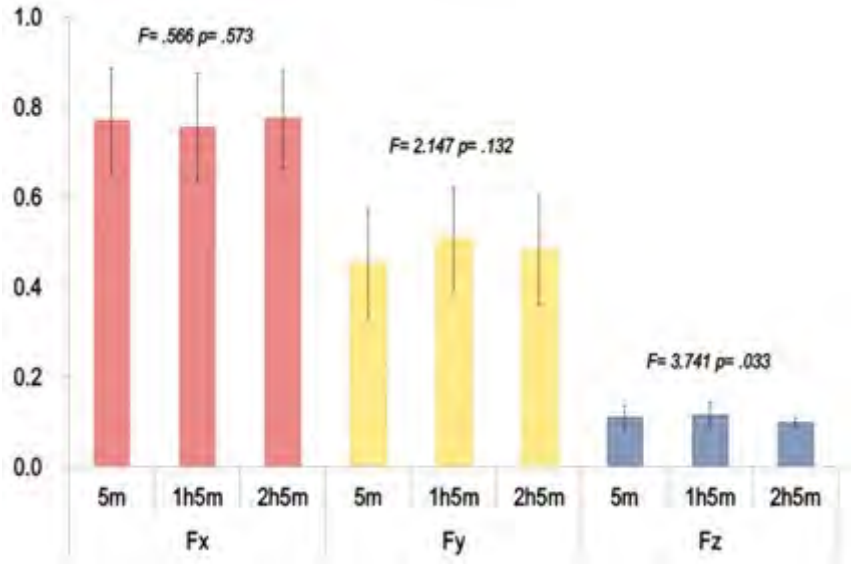
[1]Physical Education, [2]Motion Innovation Centre, [3]Health and Exercise Science, Korea National Sport University, Seoul, Korea, Republic Of

Introduction and Objectives: Ground reaction force (GRF) is a good indicator for observing the changes in velocity of the body during human locomotion. Recent technologies using an instrument treadmill allow us to measure both impact and active GRF with prolonged running on a treadmill (Jean-Benoit et al., 2011; Ryu, 2012).The investigation of GRF is essential in biomechanical research associated with injury risk and decreased stability of movement resulting from fatigue during a period of prolonged running. However, little research has examined variability of GRF that occurs with prolonged running. Variability of movement is critical and natural in human movement and it may actually be an adaptation needed for the flexibility to respond to the altered circumstance of the task (Preatoni et al., 2014). Therefore, the purpose of this study was to investigate the variability of GRF presented in timed series via a nonlinear analysis during prolonged running at three different lapsed times. It was hypothesized that an increase in running time will affect the variability of GRF during a period of prolonged running.

Methods: Nineteen healthy young males participated in this study. The subjects ran on an instrumented treadmill (Bertec, USA) at their preferred running speed (mean=2.5m/s) for 2.16 hours. GRF data (Fx: medial-lateral, Fy: anterior-posterior, and Fz: vertical) were collected for forty continuous footfalls at five, sixty-five, and one hundred and twenty-five minutes, respectively. Approximate Entropy (ApEn) technique after surrogate time series on the GRF data was applied to assess the variability for each of the running time conditions. A one-way repeated measure (ANOVA) was performed to compare the differences in ApEn values of GRF components between the running time conditions. The level of significance was set at $P < .05$.

Results: The findings indicated that among three GRF components the mean variability of Fz showed significant decreases after 2 hours running ($p < .05$). However, there were no significant changes in mean variability for the Fx and Fy components (Fig.1). Thus, it appeared that movement of segments occurring in a vertical direction after 2 hours of running during a prolonged run may be less flexible and adaptable to unpredictable environmental changes. In other words, fatigue resulting from increasing running time is linked to more regularity, but less complexity in vertical movement during prolonged running (Lipsitz, 2002). We hypothesized that this may be one of a runners' movement strategies to adapt to increased fatigue during running.

Figure:



Caption: Figure 1. Average variability (ApEn) of GRF at three time intervals (Fx: medial-lateral, Fy: anterior-posterior, Fz: vertical).

Conclusion:

Our findings indicated that Fz is more easily reproduced, whereas the reliability in Fx and Fy components are less effective because of a higher frequency compared with Fz (Ryu, 2012).Finally, among the three GRF components, Fz is the most reliable biomechanical variable when it is used to discriminate a certain abnormality of motion among different clinical populations because of the high repeatability of the signal (Preatoni et al., 2014).

DEVELOPMENT OF AN ADVANCED COMPUTER-BASED GAIT TRAINING TOOL

H John Yack [1,*]

[1]Physical Therapy & Rehab Sci, University of Iowa, Iowa City, United States

Introduction and Objectives: In spite of observational gait analysis being commonly used by clinicians to assess gait deviations, previous research has shown that the reliability and validity of observational gait analysis is not very good. While a number of strategies have been developed to document observed deviations, we are not aware of any training tools with the goal of improving observational skills. The goal of this collaborative effort is to develop a training tool that will improve the observational skills of clinicians performing gait analysis.

Methods: Conventional 3-D MoCap walking data was capture on a variety of patients, seen at the Military Performance Laboratory and the Orthopedic Gait Analysis Laboratory, representing a spectrum of gait deviations. These data were translated for input into the digital human avatar (Santos™, Center for Computer-Aided Design), which allows image form and view manipulations.Testing and training modules were developed that provided a dedicated environment. Testing environments enabled the viewing of multiple gait deviations with question sequences that assessed the user's observational skills. Training environments enabled the viewing of multiple gait sequences with the user manipulating static images that represented specific temporal events in the gait cycle. Immediate feedback is provided on how successful these manipulations were compared to the actual images. Thus far, a limited number physical therapy students and clinicians have tested various aspects of the testing and training tools in a web-based environment.

Results: Testing modules, assessed before training, showed clinicians were not able to consistently assess range of motion changes of less than 10 degrees. This was verified in analyses that showed associations between the magnitude of the deviation and the ability to detect the deviation (R^2=.25). These modules also demonstrated a sensitivity that should enable the detection of improvements resulting from using the training tool, something that is currently under investigation.

Conclusion: The development of a training tool offers the possibility of improving the observational skills of clinicians who perform gait analysis.

VARIABILITY, ASYMMETRY AND BILATERAL COORDINATION OF GAIT IN WOMEN WITH FIBROMYALGIA

Jose Heredia-Jimenez [1,*] Maria Eva Orantes-Gonzalez [1] Victor Soto-Hermoso [1]

[1] Physical Education & Sports, University of Granada, Granada, Spain

Introduction and Objectives: Fibromyalgia (FM) is characterized by widespread musculoskeletal pain of at least three months' duration, fatigue, poor sleep and tenderness on palpation in at least 11 of 18 specific tender point sites[1]. Measurements of temporal and spatial parameters of gait are of recognized clinical relevance in the assessment of motor pathologies [2] and commonly used for the identification of gait disorders[3]. But there are a few studies that utilized the gait disorder in patient with FM, reporting that the FM syndrome also affects several gait parameters and different muscle recruitment patterns. [4,5]

The aim of the present study was to assess if there are differences in spatio-temporal variables, variability, asymmetry and bilateral coordination of gait (PCI) between women affected by FM and healthy women.

Methods: We studied 55 FM women and 44 healthy women. Gait analysis was performed using an instrumented walkway (GAITRite system) at a confortable walking speed. Spatio temporal variables, variability of gait, gait asymmetry index and bilateral coordination of gait (PCI) were measured.

We calculated the coefficient of variation (CV) of swing time (CV_SW), stride length (CV_SL) and Step width (SWth) using the formula:

CV = 100 X standard deviation/mean

gait asymmetry was evaluated according to Patterson et al. [6] and coordination index according to Plotnik et al. [7]

Results: FM patients present significant differences in kinematics variables. In relation with variability and PCI, the FM patients present worse values. Gait asymmetry not presented differencess between groups (table 1).

Conclusion: We consider that variability and bilateral motor control of gait may be particularly sensitive to the effects of FM at any walking speed condition than kinematics variables. Variability and PCI should be a strong test that complemented the evaluation of FM patients and confirm the motor dysfunctions of those patients across of diagnosis and gait evaluation.

Table:

Variables	FM Mean (SD)	C Mean (SD)	p value
Gait velocity (cm/s)	109.0 (20.5)	139.2(16.8)	< 0.001
Cadence (steps/min)	109.5 (12.6)	124.5(8.7)	< 0.001
Stride length (cm)	119.1 (14.7)	134.2(11.7)	< 0.001

Swing phase (%)	36.6 (2.2)	39.0(1.4)	**< 0.001**
Stance phase (%)	63.4 (2.2)	61.0(1.4)	**< 0.001**
Single support (%)	36.6 (2.2)	39.0(1.4)	**< 0.001**
Double support (%)	26.7 (4.4)	22.1(2.8)	**< 0.001**

PILOT STUDY: SCAPULAR KINEMATICS DURING OSCILLATORY ARM MOVEMENTS USING FISIO FLEX SANNY™ EXERCISE DEVICE

Camila C. Biazotto [1,*] Kevin McQuade [2] Anamaria Oliveira [3]

[1]Department of Rehabilitation Medicine, School of Medicine, University of São Paulo, Ribeirão Preto Medical School, Ribeirão Preto, Brazil, [2]Department of Rehabilitation Medicine, School of Medicine, University of Washington, Seattle, WA, USA, Washington, United States, [3]Graduation Program Rehabilitation and Functional Performance, University of São Paulo, Ribeirão Preto Medical School, Ribeirão Preto, Brazil

Introduction and Objectives: Low frequency vibration transmitted through the human body is used in different areas to achieve goals of physical training and rehabilitation [1,2]. An oscillatory pole is a device (similar to Bodyblade™, USA) with elastic properties that provides oscillation through rhythmic movements with low frequency vibration directly delivery to upper limb. The device operates like a mass spring oscillator, where person pushes and pulls the center of the pole while the distal ends flex back and forth providing inertial resistance based on the pole stiffness. This results in rapid eccentric and concentric contractions, of distal and proximal musculature [2,3,4]. Despite widespread use of this device in training and rehabilitation, and claims for improved scapular stability, there are no studies that have examined the acute effect of these types of oscillatory exercises on scapular kinematics. The aim of this pilot study is to analyze acute effect of exercises with oscillatory pole on scapular kinematics. Secondary aim is verify the oscillatory pole median frequency and the frequency delivery to upper limb during exercises.

Methods: Four volunteers without any symptoms in the upper limbs, or previous history of trauma or surgery in the joints of the shoulder/cervical/thoracic spine participated. Three-dimensional kinematics were recorded using Liberty™ electromagnetic tracking system (Polhemus Inc, Colchester, VT). To verify the pole frequency three sensors EMG TrignoTM Wireless System (Delsys Inc. Boston, MA) configured like accelerometers were used attached to the central grip, the extremity of the pole and to participant dominant hand. Statistical analyses were performed using the IBM SPSS software v.16.0 (Chicago, IL, USA) and Excell program (Microsoft Corporation). Exercises were performed with oscillatory pole Fisio Flex Sanny ™, Brazil. Device manual was consulted and virtual contact was made but no oscillation frequency information was provided by device manufacturer. First exercise was performed bimanually with both hands holding pole in front of chest at 90º shoulder flexion, forearms pronated and pole horizontal oscillating in transverse plane parallel to the ground. Second exercise was unilateral with the shoulder at 90° flexion, forearm neutral and pole vertical oscillating in sagittal plane, perpendicular to the ground. The exercise was repeated for both left and right sides. Three repetitions of each exercise were performed for 10 seconds each. Scapular kinematics relative to the thorax was defined using YX'Z" Euler rotations following International Society of Biomechanics recommendations [5]. To evaluate scapular kinematics during the exercises the amplitude of movement in degrees of internal/external rotation, upward/downward rotation, and anterior/posterior tilt were described with median values and standard deviation. Student t-test was used to evaluate differences between dominant and no-dominant limb during the same exercise and between the two exercises with the same limb. A confidence interval of 95% was assumed with a significance level of $p \leq 0.05$.

Results: Median oscillatory frequencies during exercises were 4.5 Hz on the pole distal ends, 4.3 Hz on the central grip and 3Hz on the hand during exercise 1 and 2. Other studies with different oscillatory devices show similar results [3,4]. No statistical differences between dominant and no-dominant limb during the same exercise and between the two exercises with the same limb were observed ($p \geq 0.05$). Table 1 summarizes the scapula rotation amplitudes and Student t-test results to comparisons between dominant and no-dominant limb.

Conclusion: According to preliminary analyses of means and standard deviations values, results suggest that effects of exercises with oscillatory pole are different according to three scapulae movement axes. No differences between dominant and no-dominant scapulae during the exercises were found. During three exercises both scapulae had more variation on superior and inferior rotation, however this rotation had the larger standard deviation. While the lowest variation was observed to anterior and posterior tilt.

Table:

	Exercise 1			Exercise 2		
	Dominant limb	No dominant limb		Dominant Limb	No dominant limb	
	(Mean±SD)	(Mean±SD)	p value	(Mean±SD)	(Mean±SD)	p value
Upward/Downward rotation	8.05 ± 4.54	8.46 ± 4.52	0.587	9,67 ± 3.73	10,56 ± 7.85	0.123
Internal/external rotation	6.94 ± 4.46	5.55 ± 2.81	0.605	6,41 ± 1.43	9,66 ± 2.96	0.816
Anterior/Posterior tilt	3.65 ± 1.40	3.92 ± 0.79	0.516	3,07 ± 0.91	4,41 ± 0.96	0.162

SPEED MODELLING OF RELATIVE GAIT PHASE DURATIONS

Felix Hebenstreit [1 2 3,*] Andreas Leibold [1] Sebastian Krinner [3] Götz Welsch [3] Matthias Lochmann [2] Bjoern Eskofier [1]

[1]Digital Sports Group, [2]Institute of Sport Science and Sport, Friedrich-Alexander University Erlangen-Nürnberg (FAU), [3]Department of Trauma Surgery, University Hospital Erlangen, Erlangen, Germany

Introduction and Objectives: Gait speed is an important factor to consider when performing biomechanical studies or diagnosing gait disorders. As an example, Andriacchi et al. showed that healthy subjects could be distinguished from injured and rehabilitating patients by evaluating spatiotemporal parameters such as stance and swing time during gait at different speeds [1].

Perrys common definition of the gait cycle separates the gait cycle into functional sub phases [2]. However, Perry stated no specific speeds for the definition of these sub phases. Other studies indicated that biomechanical parameters depend on gait speed. One study showed the dependency of kinematics and kinetics on self-selected speeds in five different speed ranges [3]. They described changes of the double support, single support and swing phases in these speed ranges. A recent study investigated gait sub phase variations for three different self-selected speeds [4].

As detailed analyses of the changes of all stance sub phase durations with speed are still missing, we quantitatively determined the durations of the loading response, mid stance, terminal stance, pre swing, total stance and total swing phase. These phases can be separated by the events “heel strike”, “toe off” and “heel off” [2] (figure 1).

The purpose of this study was then to model the relative durations of the gait sub phases (as % of one gait cycle) with speed in a large speed range at a high resolution and based on a large dataset of steps.

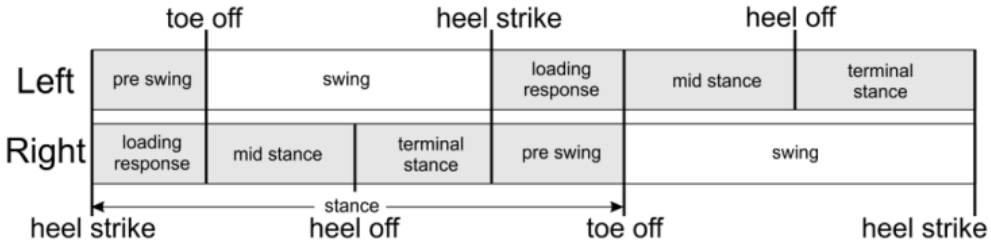
Methods: 21 healthy subjects (10 male, 11 female, age: 23.8 yrs ± 3.3 yrs, height: 172.8 cm ± 9.4 cm, mass: 66.6 kg ± 10.9 kg) gave informed consent before participating. The local ethical committee approved this study. We attached six reflective markers to each foot above the first, second and fifth metatarsal heads, on the calcaneus and on the lateral and medial malleoli. All subjects wore the same type of shoe. We acquired the markers’ positions using a Qualisys infrared system (8 cameras, 200 Hz sampling rate) and the ground reaction forces using a Bertec instrumented split-belt treadmill (1000 Hz sampling rate).

The subjects walked for two minutes on the treadmill for accommodation. Thereafter they walked without stopping at 12 speeds in the range of 0.6 m/s to 1.7 m/s with 0.1 m/s increments. We randomized the speed order with a trend to higher speeds at the end of the session to minimize fatigue effects. Each trial at one speed lasted 60 s.

Pre-processing was performed in Visual3D (C-Motion) and consisted of force drift correction and force and marker position filtering using a 2nd order Butterworth filter (6 Hz cut-off frequency). A 20 N threshold on the vertical component of the ground reaction force yielded the events “heel strike” and “toe off”. We applied a threshold of 0.1 m/s to the vertical velocity of the calcaneus marker to detect the “heel off” event [5]. The relative sub phase durations were then calculated in MATLAB R2013b. We calculated the mean for each walking trial and foot of every individual subject, performed a linear regression with these averaged durations (model: $f(x) = ax+b$, $f(x)$: duration, x: gait speed) and determined the coefficient of determination R^2.

Results: We acquired 25306 steps in total with 615 steps being excluded by hand when the subject stepped on both belts. The results of the regression are stated in table 1. The stance phase duration decreased by 0.3 % and the swing phase duration increased by 0.3 % absolutely per 0.1 m/s speed increase. The loading response and pre swing phase decreased by 0.3 %, the mid stance decreased by 1.6 % and the terminal stance phase increased by 1.8 % per 0.1 m/s speed increase. The general trend of decreasing stance and increasing swing time is consistent with the literature. The regression parameters indicate a redistribution of the mid stance phase towards the terminal stance phase.

Figure:



Caption: Gait cycle and the analyzed sub phases.

Conclusion: This study showed an effect of gait speed on the relative gait sub phase durations. The linear modelling indicated an empirical rule of thumb that can be used to estimate gait phase durations. The results show that the individual gait speed should be regarded in biomechanical investigations. The results from this study may be used as a reference for interpreting gait data or in orthopedic applications. In the future, the determination of model parameters for different patient populations might help to characterize and understand biomechanical mechanisms of specific diseases.

Table:

Phase	a [%/(m/s)]	b [%]	R^2
Stance	-3.2	68.0	0.52
Swing	3.4	31.7	0.56
Loading response	-3.2	17.9	0.56
Mid stance	-15.7	41.4	0.39
Terminal stance	17.7	-10.3	0.79
Pre swing	-3.1	17.9	0.56

SMOOTHING OR FILTERING MARKER TRAJECTORIES? THE EFFECTS ON CALCULATED JOINT MOMENTS

Annaclaudia Montanino [1,*] Luca Modenese [2] Anantharaman Gopalakrishnan [3 4] Nicola Petrone [5] Andrew T. M. Phillips [6]

[1]Department of Information Engineering DEI, University of Padova, Padova, Italy, [2]Centre for Musculoskeletal Research, Griffith University, Griffith, Australia, [3]Department of Civil and Environmental Engineering, Imperial College London, [4]The Royal British Legion Centre for Blast Injury Studies at Imperial College, London, United Kingdom, [5]Department of Industrial Engineering, University of Padova, Padova, Italy, [6]Structural Biomechanics, Department of Civil and Environmental Engineering, Imperial College London, London, United Kingdom

Introduction and Objectives: In the field of biomechanical analysis, it is common practise to use motion capture systems to quantify the motion of body segments based on the trajectories of skin markers. The obtained measurements, even if accurate, include a noise component that is necessary to take into account especially when investigating the dynamics of the system. This evaluation includes a derivation process to calculate accelerations which is known to amplify the noise content.

Many filtering techniques have been proposed in literature. The most traditional one is the low-pass Butterworth filter [1], which relies on an arbitrary choice of a cut-off frequency since the signal and noise bandwidth are unknown a priori and the nature of the signal of interest is non stationary. Another feasible approach is based on singular spectrum analysis (SSA) in its sequential version [2]. This smoothing algorithm is free from assumptions on the original signal and does not involve any arbitrarily set parameters apart from the parameter which describes the stopping criterion.

It has been demonstrated that 6Hz is an appropriate cut-off frequency for walking data [1], but there is no analogous evidence for the appropriate cut-off frequencies for the analysis of other daily living activities such as stair climbing. The objective of this study is therefore to compare the SSA and standard low-pass filter based on joint moments calculated for daily living activities.

Methods: To compare the SSA and the standard low-pass approaches applied to marker trajectories, an inverse dynamics analysis using OpenSim [3] was performed on the same original dataset.

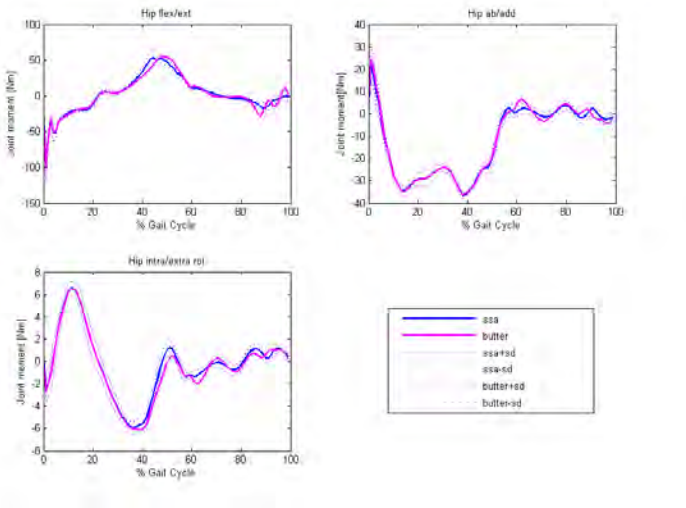
The dataset includes data collected during 10 walking trials and 8 stair climbing trials of a healthy female subject. A Vicon System of 10 cameras (sampling rate: 100Hz) was used to track the markers and 3 Kistler 9286BA platforms were used to measure the ground reaction forces (sampling rate: 1000Hz). The given 3D trajectories of 57 markers were first labelled and gap filled using Vicon Nexus software and cloned: the trajectory components of the first clone were filtered using a 4^{th} order zero-lag low-pass Butterworth filter with cut-off frequency set at 6Hz, while the trajectory components of the other clone were iteratively smoothed with the SSA algorithm presented in [2] until the stopping criterion was met, that is when the difference between the RMS of the accelerations computed in two consecutive iterations is less than 1%, to avoid over smoothing of the acceleration.

Joint angles for a full body model based on [4] were obtained for both cloned datasets using the inverse kinematics tool available in OpenSim. In the adopted model the hip joint is represented as a ball socket joint and has 3 degrees of freedom, whereas both knee and ankle joints are modelled as hinge joints.

The computed joint kinematics and measured ground reaction forces, were inputted to an OpenSim inverse dynamics analysis to calculate the joint moments. The similarity between the obtained curves was quantified by computing cross-correlations for each pair of corresponding moments.

Results: The mean cross-correlation coefficient for the 10 walking trials is 0.98±0.01 while for the 8 stairs trials is 0.99±0.01, denoting practically equivalent results between the two processing methodologies. Hip joint average curves and standard deviations are presented in the Figure. Additional activities from the dataset (stair descending, sitting and standing from a chair) are currently being processed.

Figure:



Conclusion: The purpose of this study was to compare inverse dynamics results obtained from 3D marker trajectories processed either with a low-pass Butterworth filter or with a SSA smoothing.

Our results did not indicate a significant difference between the SSA and the low-pass filtering approaches for the inspected activities, however, it must be noted that the inverse kinematics algorithm [5] calculates joint angles searching for the optimal pose of the multibody model thus relying not only on the position of the global markers, but also on the joint constraints. As a consequence, differences between the two approaches under consideration may be mitigated.

Although SSA does not rely on arbitrary choices, as the resulting moments obtained by the two approaches are close to equivalent both for walking and stair climbing, the use of the traditional filtering procedure with cut-off frequency of 6Hz seems justified for these activities. Further study could take into account other daily living activities such as running, whose derived joint moments could potentially be more affected by the computed accelerations, with the inertial contribution being more significant.

PO-0243

EFFECTS OF LEADING LIMB AND OBSTACLE HEIGHT ON THE CONTROL OF THE END-POINT AND BODY'S CENTER OF MASS MOTION DURING SIDE-LOADED OBSTACLE CROSSING

Chih-Chung Hu [1 2] Tung-Wu Lu [1 3,*] David Tzewei Lin [1] Ching-Ru Chen [1]

[1]Institute of Biomedical Engineering, National Taiwan University, [2]Department of Mechanical Engineering, Ming Chi University of Technology, [3]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Tripping and loss of balance are two major causes of falls during obstacle-crossing, especially in the elderly. Precise end-point control (sufficient foot clearance over the obstacle) and good balance control (body's center of mass (COM) control) are critical for crossing obstacles safely. Under side-loaded conditions such as carrying a handbag, the control of the end-point and COM may be more difficult owing to the asymmetrical mechanical challenges of the side-loads. Proper choice of the leading limb (ipsilateral or contralateral to the loaded side) may be helpful for better control of obstacle crossing. The current study aimed to investigate the effects of leading limb and obstacle height on the control of the end-point and body's COM motion during side-loaded obstacle-crossing in young healthy adults.

Methods: Ten young healthy adults (age: 24.4±4.71 years, height: 168.6±5.97 cm and mass: 62.7±4.71 kg) walked and crossed obstacles of heights of 10%, 20% and 30% of their leg lengths (LL) while carrying a constant load (dumbbell) of 4.5 Kg by their right hand. All subjects were judged to be right-handed by the Edinburgh Handedness Inventory. Forty-three infrared retroreflective markers were placed on specific anatomical landmarks to track the motions of the body segments and two markers were attached to the ends of the dumbbell. A 7-camera motion analysis system (Vicon 512, Oxford Metrics, U.K.) and three force plates (AMTI, U.S.A.) were used to measure the marker trajectories and ground reaction forces. The body's COM position was calculated as the weighted sum of those of all the body segments. Toe clearances were calculated as the vertical distance between the toe marker and the obstacle when the toe was directly above the obstacle. The positions of the center of pressure (COP) were calculated from the forceplate data. The COM-COP inclination angles (IA) were calculated as the angles between the COM-COP vector and the vertical in the sagittal and frontal planes, giving sagittal IA and frontal IA respectively. Two-way mixed-model ANOVA with one between-subject factor (obstacle height) and one within-subject factor (leading limbs) was performed for the toe clearance and IA (α=0.05). SPSS was used for all statistical analysis.

Results: No interactions between the main factors were found. Toe clearances decreased significantly with increasing obstacle height ($p = 0.004$) but no significant differences were found between the ipsilateral and contralateral limb conditions ($p = 0.419$) (Table 1). The frontal IA during crossing with the contralateral limb leading was statistically greater than that with the ipsilateral limb leading ($p = 0.025$) but no significant height effect was found (Table 1). No significant height or limb effects were found for sagittal IA ($p>0.05$).

Conclusion: The height of obstacle has significant effect on toe clearances, but not on body's COM motion during side-loading obstacle crossing, suggesting that balance control is maintained with compromised end-point control when facing

higher obstacles. Different strategies were found when crossing with different limb leading. During obstacle crossing with the contralateral limb leading, when the COM and the side load were on different sides of the trailing stance limb, the COM was displaced away from the stance limb to counteract the effects of the side load, leading to larger frontal IA. On the other hand, with the ipsilateral limb leading, when the COM and the side load were on the same side to the trailing stance limb, the COM was displaced towards the stance limb to decrease the lever arms of the COM and the side load in order to maintain the body's stability. It appears that with less frontal inclinations ipsilateral limb leading is preferable to contralateral limb during side-loaded obstacle crossing.

Table:

Height (LL)	Ipsilateral limb leading			Contralateral limb leading		
	Toe Clearance (mm)	Fontal IA (degree)	Sagittal IA (degree)	Toe Clearance (mm)	Frontal IA (degree)	Sagittal IA (degree)
10%	201.77 (9.08)*	3.23 (0.65)**	2.56 (0.38)	211.54 (13.09)*	4.39 (0.37)**	0.67 (0.21)
20%	188.66 (11.31)*	3.27 (0.58)**	1.06 (0.35)	186.07 (14.85)*	4.90 (0.22)**	0.78 (0.42)
30%	153.11 (10.26)*	3.61 (0.38)**	1.29 (0.60)	168.32 (16.13)*	3.85 (0.34)**	1.42 (0.48)

* indicates a significant height effect on toe clearances ($p = 0.004$)

** indicates a significant leading limb effect on frontal IA ($p = 0.025$)

Caption: Table 1: Means and standard deviations of the toe clearance, frontal IA and sagittal IA when crossing obstacles of three different heights with the ipsilateral or contralateral limb leading.

PO-0244

METHODOLOGY FOR COMPUTING NEW SEGMENT ROTATION AXIS

Yuta Kawamoto [1,*] Takahito Suzuki [2] Shinsuke Yoshioka [1] Senshi Fukashiro [1]

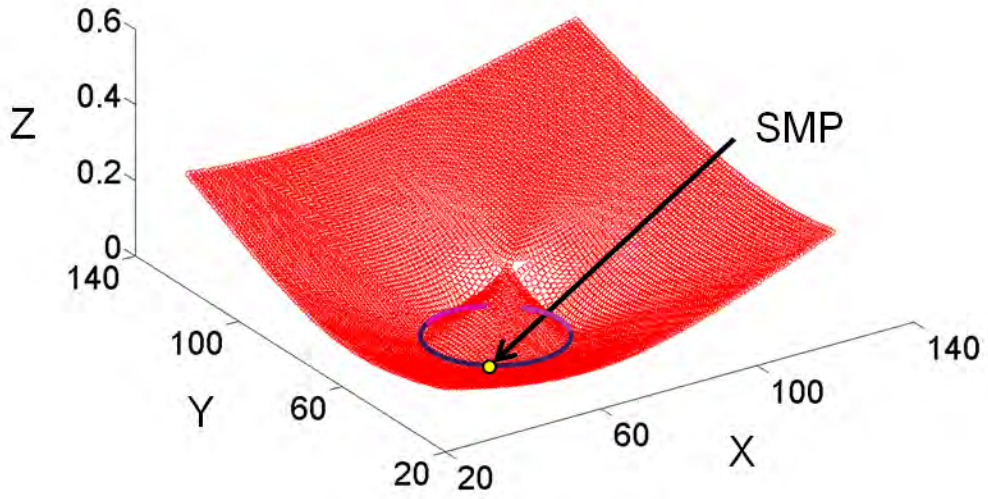
[1]Department of Life Sciences, The university of Tokyo, Tokyo, [2]Department of Human Sciences, Kanagawa University, Kanagawa, Japan

Introduction and Objectives: Most of segment movements consist of translation and rotation, and the position of rotation axis was debatable. In many cases, the body segment rotation axis was placed on its center of mass (COM). However, a body segment usually does not rotate about its COM, and the rotation axis changes position on the segment. When axis was placed on instantaneous screw axis (ISA), it was able to change position on the segment [1], but the translation perpendicular to ISA was incorporated into the rotation about ISA. Therefore the new rotation axis, about which segment actually rotated and which was able to separate translation, was needed. The purposes of this study were to define new rotation axis and to develop the searching procedure for computing it. The procedure based on mathematical predictions was confirmed by simulation.

Methods: A point that moved straight in the global coordinate system (straight moving point: SMP) was defined as the new rotation center, in two-dimensional segment movement. SMP would be searched with the location of instantaneous center of rotation (ICR), which is the point with zero velocity for a particular instant and which ISA passes thorough in two-dimensional movement. This searching procedure was based on following mathematical predictions. First many points which moved almost straight were distributed on the circle with a gap. Second ICR existed at the gap of the circle. Third, SMP was on the circle. The prediction was confirmed by the following simulations. In simulation 1, velocity and angular velocity of the segment were constant. In simulation 2, they were varied linearly. Position of SMP was selected as below. When a point attached to the segment coordinate system passed certain points on the global coordinate system at specific time interval, the sum of distances between the pass points and regression line of them was computed as the objective function value of the point attached to segment coordinate system. Then, a point that had the minimum value was selected as SMP. In the three-dimensional movement, axis was able to be defined as below. First, to compute ISA and to eliminate the translation along ISA, the three-dimensional movement reduces to two-dimensional one. And then, SMP position was computed and axis was on SMP along ISA. The movement was represented with linear movement of SMP, rotation about SMP and translation along ISA.

Results: Figure 1 showed a typical graph of objective function values in simulation 1. X and Y coordinates coincided with local coordinates of the segment. The graphs in both simulation 1 and 2 always formed a circle with a gap as seen in the figure. The circle meant there were many points which moved almost straight. ICR and SMP existed on the gap of the circle and on the circle, respectively. Therefore, using ICR the position of the circle was searched easily and SMP position was able to be computed as the point that has the minimum objective function value on the circle. SMP position was accurately computed and the error of SMP was within 1% of the square-shaped segment height.

Figure:



Caption: Figure 1 Typical graph of objective function values in simulation 1

Conclusion: SMP was defined as a position of segment rotation axis. Mathematical predictions were confirmed by the simulation. Based on the predictions, SMP position was accurately computed. SMP represented the position about which segment actually rotated and could separate translational component. On the other hand, COM was not the position about which segment actually rotated and with ISA translation was incorporated into simple rotation. Therefore SMP had advantage over COM and ISA in representing the rigid body movement. Segment movements in various sports consist of translation and rotation. SMP can apply to those movements and it would offer new insight into segment kinematics.

GAIT PATTERN RECOGNITION IN CEREBRAL PALSY PATIENTS AND NORMAL CHILDREN USING NEURAL NETWORK MODELLING

Jan Muhammad [1]Sheila Gibbs [1]Rami Abboud [1]Weijie Wang [1,*]

[1]University of Dundee, Dundee, United Kingdom

Introduction and Objectives: Interpretation of gait patterns from 3D gait data is challengeable as there are many kinematic and kinetic parameters involved. Artificial neural network is a type of computer model which works similar to human's central nervous system capable of learning from input data and then use the obtained knowledge to predict gait patterns. The aim of this study was to build neural network models which can recognise gait patterns from the pre- and post-treated patients and normal children.

Methods: Twenty-eight patients with cerebral palsy were recruited as subjects whose gait data were collected in pre- and post-treatment. Twenty-six normal children participated in this study as control group. All subjects' gait data were analysed to obtain the gait parameters and kinetic and kinematic parameters of hip, knee and ankle joints in three planes of both limbs. The gait data were collected using a Vicon® 12 FX digital camera motion capture system (Oxford, UK). Three best trials were chosen for each patient from pre- and post-treatment sessions, respectively and three for each healthy one as well. The gait data were categorised as three patterns, i.e. normal, pre- and post-treatments and used as input to construct neural network models. A total of 350 trials were split into 70% and 30% to train and test the models, respectively. Different models were built using different combinations of gait and joint parameters.

Results: The neural network models created using all parameters in both injection and surgical groups produced the high quality results, both being over 95% correct ratio in training samples and over 90% correct ratio in testing samples, respectively. The results showed that the models using all parameters or using the joint angles and moments could predict the gait patterns with approximately 95% accuracy. The models using joint power and moments had lower rate in recognition of gait patterns with approximately 70% - 90% successful ratios. The models created using kinetic parameters (force, power & moment) in injection group and the model created using angles and gait parameters in surgical group, yielded approximately 95% correct prediction in training samples and 90% in testing samples. In surgical group, the model created using joint angles and gait parameters predicted with 95% and 90% accuracy in training and testing samples, respectively.

Conclusion: The neural network models can be constructed using joint and gait parameters in cerebral palsy patients in pre- and post-treatments and healthy subject. The built neural network models show highly correct ratios in predicting gait patterns for CP patients in both injection and surgery groups and in different treatment periods. We can conclude that the neural network modelling is a robust and a reliable method which could help clinicians to interpret and assess patient gait in clinical gait analysis.

ANALYSIS OF ACTION SPORTS WITH A MOTION RECORDING SYSTEMS BASED ON 9-DEGREES SENSORS AND GPS

K Ishida [1,*]

[1]Hiroshima Institute of Technology, Hiroshima, Japan

Introduction and Objectives: We develop a new motion recording systems based on GPS and 9-degrees sensors which is composed of 3 axis accelerometer, 3 axis gyroscope, and 3 axis digital compass. Deploying the systems, we analyze turn maneuver on a half-pipe with skateboard, inline skate, and BMX (Bicycle Motocross).

Methods: We put the recording device on an athlete's head, waist, right foot, and left foot. The device is composed of microcomputer (Arduino Fio), accelerometer and gyroscope (MPU6050), digital compass (HMC5883L), and GPS (MTK3339). The motion and location data is stored in micro SD-card. The recording data is processed by a pre-processing software. The software converts date and time into timestamp in the data. It also synchronizes and normalizes the timestamp on the data collected from multiple devices on head, waist, right foot, and left foot. After the normalization, it detects time series of each action automatically. Based on the pre-processed data, we define a distance function between each pair of time series of two runs in order to identify varieties of turn maneuver on a 13 feet halfpipe. The function is defined by sum of squared difference between pair of autocorrelation functions of two action time series data. In terms of turn skill on a halfpipe, we find three types of riding level on a halfpipe, i.e, beginner, intermediate, and advanced. Beginner is defined as turning on the concave of a halfpipe. Intermediate is defined as turning on the vertical surface of a halfpipe. Advanced is defined as making air turn over the coping of a halfpipe. We can observe different type of autocorrelation function between different riding levels.

Results: An experiment was conducted on a 13 feet halfpipe with skateboard, inline skate, and BMX. There were total of 18 athletes who participated the experiment. They did three or four ridings. Each riding is composed of 6 to 8 round trips on the halfpipe. We got 57 riding data excluding unsuccessful ridings. All distances between each pair of time series of runs is calculated based on the proposed method of autocorrelation. For comparison, we also calculated ordinal distances measure based on statistical indexes, i.e. average and standard deviation on each time series of riding data. In order to evaluate the two distances measure, we defined precision of ranking based on each distance. The precision is defined by s / n, where n is the total number of same type riding data in the data set and s is the number of same type riding data in the top n ranking list. In terms of the precision, the average score based on proposed distance is 0.72563 and standard deviation is 0.187456. On the other hand, the average score based on the ordinal distance is 0.674764 and the standard deviation is 0.20836. Furthermore, to have a visual confirmation of the advantage of the proposed method, we illustrate two dendrograms of hierarchical clustering with ward method for the proposed method and ordinal method. According to the dendrogram of the proposed method, same type of riding data is properly classified into a same cluster. While, in that of the ordinal method, 17 riding time series were not classified into proper clusters.

Conclusion: We developed a new motion recording systems based on GPS and 9-degrees sensors which is composed of 3 axis accelerometer, 3 axis gyroscope and 3 axis digital compass. Deploying the systems, we analyzed turn maneuver on a half-pipe with skateboard, inline skate, and BMX.

PO-0248

A DYNAMIC MODEL TO COMPUTE TORQUES GENERATED BY THE SHOULDER AND THE ELBOW TO PRODUCE FORCES DURING HANDCYCLING

Abdelmajid Ousdad [1,*] Matteo Lancini [1] Giovanni Legnani [1]

[1]department of mechanical and industrial engineering, university of Brescia, Brescia, Italy

Introduction and Objectives: Handbikes are three wheel vehicles used for transportation and recreation, but also widely used in rehabilitation programs for people with reduced mobility, and in sport field for disabled persons.

In the last decades, researches have showed interest in different aspects of synchronous handcycling. Literature analyzes physiological responses with oxygen uptake, ventilation and respiratory rate to identify the mechanical efficiency [1]. Furthermore, some studies performed a biomechanical and force analysis, which conducted to the identification of two main efficiency indices. The first one is the fraction of effective force (FEF) [2], associated with the effectiveness of the force application. The second one is the postural force production index (PFPI) [3], which evaluates the force generation capacity in all directions. However, these indices do not take in account gravity, inertia and the Coriolis effects, thus presenting a limitation in the efficiency evaluation.

The aim of this study is to present a dynamic model that takes in account the contributes of gravity, inertia and Coriolis effects, in order to associate the forces measured on handles to the corresponding shoulder and elbow torques, and to determine the force manipulability ellipsoids during handcycling. This allows to correct the definition of the mentioned indices to give them more relevance.

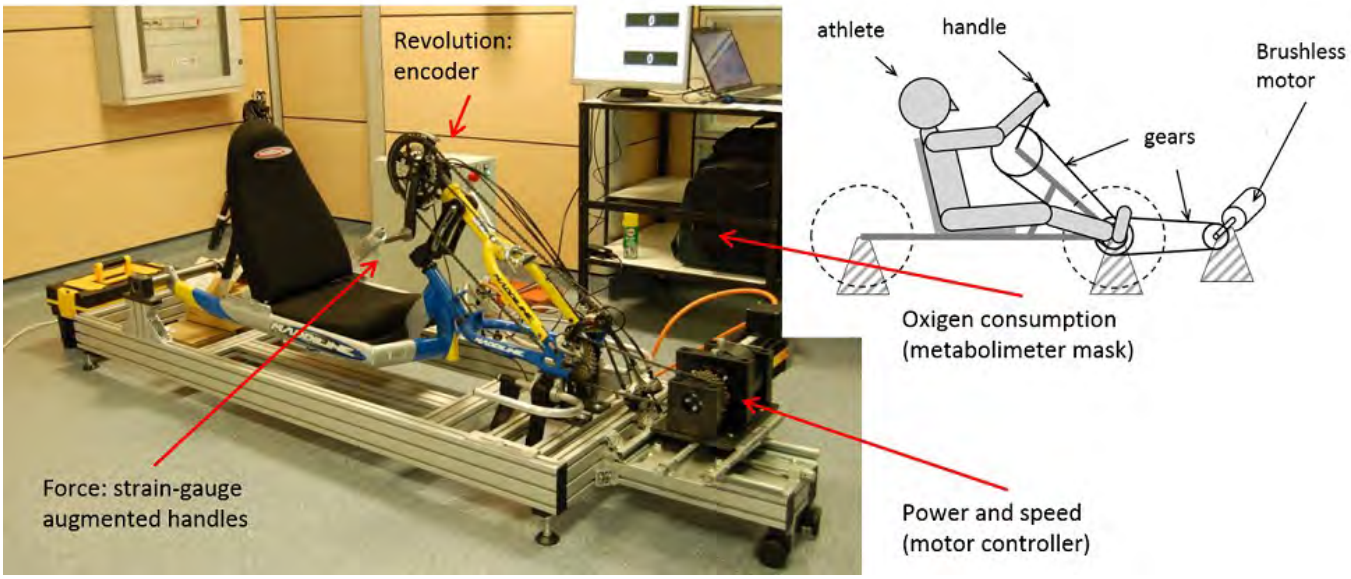
Methods: Five wheelchair dependent subjects, after giving their written informed consent, participated in the experiments. All subjects, experienced in handcycling, were asked to performe tests at a constant power. The tests were conducted in an adjustable recumbent sport Handbike which was converted in ergometer, integrating a control system that guarantees a constant output power. This device, designed and built by the university of Brescia, is equipped by two bi-axial load cell mounted on handles to measure radial and tangential components of the applied force, and an encoder to measure the angular position of the crankshaft in order to relate the measured force to the crank position (figure1). The 3D coordinates of the elbow and shoulder were determined by a vision system using passive markers. Then, anthropometric data was used to identify the dynamic parameters of arm and forearm. Finally, a dynamic model of the arm was defined [4], considering three rotations for the shoulder joint, one rotation for the elbow joint, pronosupination and two degrees of freedom (DoF). The angular position and forces were measured in cycling tests at constant power propulsion.

Results: The posture of the arms, the crank position and the force at the handle are measured with respect to the time, while velocities and accelerations are assessed by numerical differentiation. By using the dynamic model it was possible to compute torques generated by the human joints.

In order to determine the maximum voluntary joint torques that a subject may generate, we locked the crank in different angular positions and asked the subject to exert the maximum possible force. The maximum joint torques were used to determine the force manipulability ellipsoids.

In the end, we modified the definition of the mentioned indices (FEF and PFPI) by including the effect of dynamic contributions, and of the force weight, obtaining the Fraction of Effective Torque (FET) index, which assesses the efficiency of torque generation in joints, and the Inertial and Postural Force Production (IPFP) index, which evaluates the effect of inertia and the posture on the generation of force.

Figure:



Caption: Figure 1: Details of the ergometer used for the tests.

Conclusion: This study had developed an analytic method to compute joints torques generated during handcycling. The method takes into account inertia, gravity and the Coriolis effects. Furthermore, it has identified two new indices that could be used to describe and understand the performance of handbike athletes. Experimental tests confirm the effectiveness of the approach.

VALIDATION OF AN ACCELEROMETER EMBEDDED ON SMARTPHONE AGAINST A DYNAMIC LINEAR ACTUATOR

Natália Carneiro Badaró [1,*] Amanda Pe López [2] Alberto Luiz Serpa [2] Ricardo M.L Barros [1]

[1]Faculty of Physical Education, [2]Faculty of Mechanical Engineering, University of Campinas, Campinas, Brazil

Introduction and Objectives:

Inertial sensors have been increasedly used in motion analysis in clinical or performance contexts with a great variability of purposes. Sensors inside smartphones have also been proposed and tested. Most of the studies found in the literature evaluated the feasibility [2] or the validity [1] of such devices testing the measurements against the results of kinematical analysis system, commonly used to measure human motion. Considering the complexity of such kinematical systems and the problems related to define common coordinate systems, simpler and more controlled mechanical tests could provide useful information. The purpose of this study was to validate the use of the linear accelerometer embedded in a Smartphone testing those measurements against a dynamic linear actuator. The variables evaluated were the main frequency and the amplitude of acceleration of the measured signals. The smartphone was attached in a linear actuator to measure the signal. The idea of this work is to validate the smartphone sensor in order to evaluate the potencial of this device to measure human body motions.

Methods:

In order to validate the measurements of the smartphone, a linear actuator was used as reference (Gold Standard). A linear actuator is a device that creates motion in a straight line under very controlled conditions. In this test, a dynamic linear actuator INSTRON (model PL25) with nominal range of 50 mm was used. The actuator was regulated to work at different frequencies (0.5, 1, 2, 3, 4, 5, 6, 8 and 12 Hz) and amplitudes (0.3, 5.0 and 10 mm). A smartphone Samsung Galaxy SII GT-I9100 was tested. The Acceleration Sensor inside was the model K3DH with range of 19.6133 m/s^2 and a resolution of 0.0047884034 m/s^2. The Sensor Insider Pro application software was used to acquire data and export to a Matlab file format. A special device was designed to fix rigidly the smartphone to the actuator and to orient the coordinate systems of both devices accordingly. The motion in only one direction was analyzed (Y-direction in the smatphone). The experiment was performed at the Dynamic Testing Laboratory in the University of Campinas, Brazil.

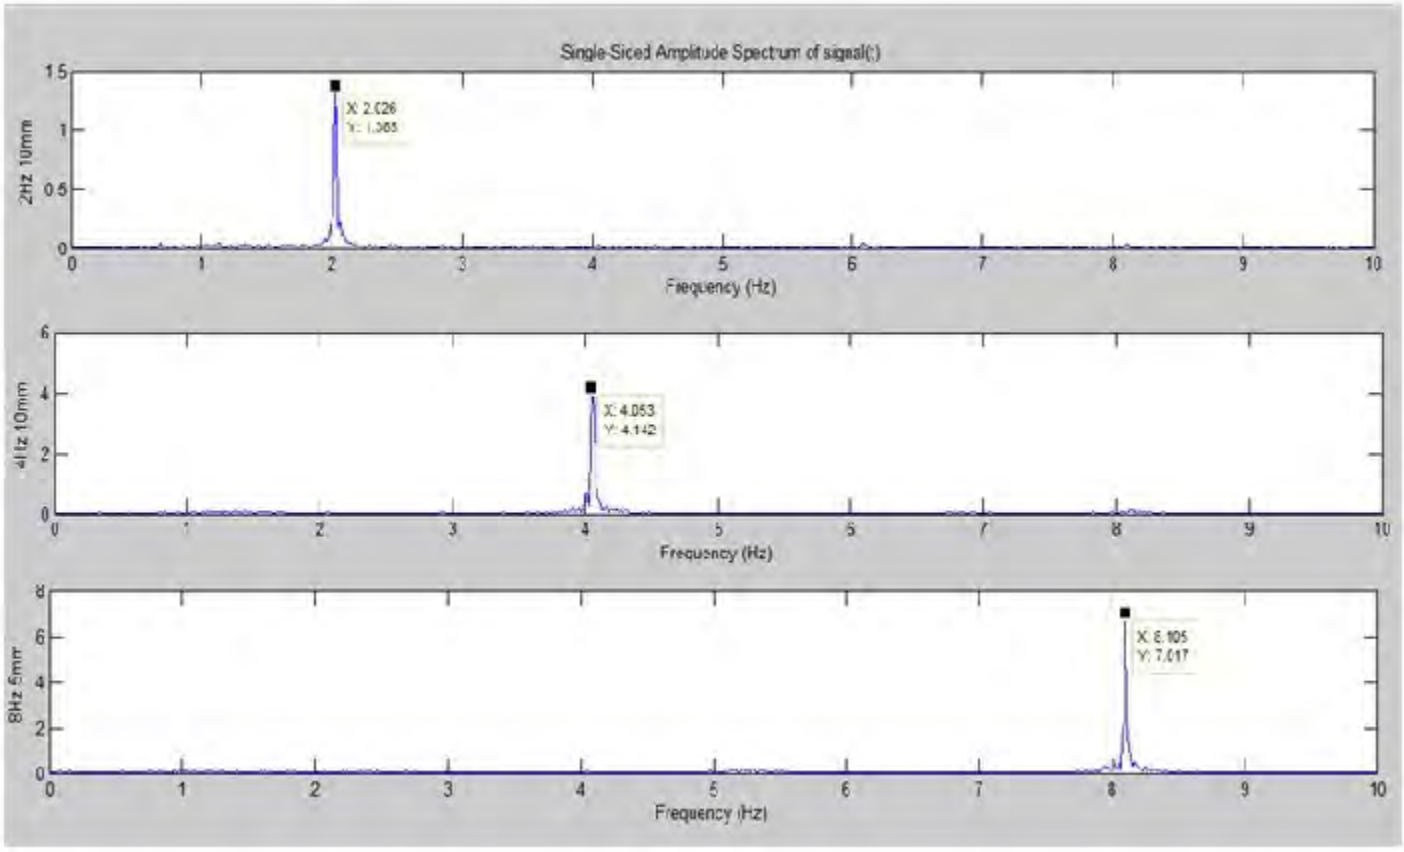
The signals were processed using spectral analysis (Fast Fourier Transform) to obtain the signal decomposition in terms of frequency. The frequency with the higher power spectral density was selected and used for comparisons. Afterward a fourth order butterworth filter with a cutoff frequency twice the selected frequency was applied to both signals. The displacement signal generated by the actuator was initially filtered and after that differentiate twice. The main frequency of motion and the average amplitude of the acceleration from both devices were compared in terms of absolute and relative errors.

Results:

Figure 1 show the single-sided amplitude spectrum of the signals recorded by the smartphone in three different tests with 2, 4 and 8 Hz and an amplitude of 10, 10 and 5 mm respectively.

The average amplitude of 1500 samples of the signal measured by the smartphone was compared with the amplitude of the actuator signal in each condition. The results are showed in Table 1.

Figure:



Caption: Figure 1: Frequency analyses of the signal with 2Hz, 4 Hz and 8 Hz and an amplitude of 10 mm, 10 mm and 5 mm respectively to obtain the main frequency.

Conclusion:

The estimates of frequency of motion provide by the smartphone are close to the expected values with relative error around 2%. However, the accelerations provided by the smartphone presented inconsistent values. It is important to take carefully these outcomes considering the possible influence of filtering and derivative procedures on the results of acceleration comparisons. It is possible that further improvements in the data processing provide measurements closest to the expected values of acceleration. In conclusion, the test designed in the present study revealed that the smartphone can measure the main frequency of motion properly however the acceleration measurements were not acceptable.

Table:

Amplitude of the actuator signal (mm)	Frequency of the actuator signal (Hz)	Frequency observed by the smartphone (Hz)	Frequency relative error (%)	Acceleration amplitude of the actuator signal (m/s^2)	Acceleration amplitude of the actuator signal (m/s^2)	Amplitude relative error (%)
10	0.5	0.51	2.00	0.099	0.102	3.03
10	1	1.01	1.00	0.395	0.663	67.84
10	2	2.02	1.00	1.573	1.881	19.58
10	3	3.05	1.66	3.505	3.475	0.86
10	4	4.05	1.25	6.077	5.699	6.22
10	5	5.06	1.20	9.288	7.740	16.66
10	6	6.07	1.16	12.982	10.369	20.12
5	8	8.10	1.25	11.166	8.808	21.11

TRUNK REFERENCE FRAMES AND THE CALCULATION OF TRUNK AND BREAST KINEMATICS IN HUMAN MOVEMENT ANALYSIS

C Mills [1,*] A Loveridge [1] A Milligan [1] J Scurr [1]

[1] University of Portsmouth, Portsmouth, United Kingdom

Introduction and Objectives: The use of the female cohort presents a unique challenge as the design of the bra used to support the breasts during physical activity compromises the positioning of the International Society of Biomechanics (ISB) recommended marker set used to create the trunk reference frame [1]. The need to develop a new trunk marker set has been highlighted [2] and should consider the location and design of the underband and bra straps; and other bra features such as neckline height. This study aimed to compare trunk and breast kinematics calculated using two existing and one new trunk marker set.

Methods: Following institutional ethical approval twelve females (mean (SD): age 23.8 (3.5) years, height 1.68 (.06) m, body mass 61.0 (5.8) kg, 32 to 34 underband with a B to D cup size) volunteered for this study. Eight trunk markers were used to define the three trunk reference frames (Figure) and an additional marker on the right nipple represented gross breast motion. Three dimensional movement of the markers were tracked using 15 optoelectronic cameras (Oqus, Qualisys, Sweden), positioned around the treadmill, sampling at 200 Hz. The participants stood statically in the anatomical position for a 2 second trial for use in the segment estimation algorithm before running bare-breasted at 2.8 m/s. Marker coordinates were recorded for five gait cycles. Markers were identified and reconstructed in Qualisys Track Manager; no data interpolation was used as marker capture success was utilised in this study to assess the suitability of each marker set. Marker coordinates from both the static and dynamic bare-breasted trials were imported into Visual 3D (C-Motion Inc, USA) and the three trunk reference frames (segments) were created. To simulate the underband when wearing an everyday or sports bra [3] both the PX and T8 markers (Figure) were removed from the raw data files (dynamic trials). These modified files were imported into Visual 3D where it was noted that the Trunk 2 segment failed to be constructed due to an insufficient number of markers, limiting its use during trials that include females wearing a breast support garment. Trunk segment capture success (%), segment origin instability (cm), segmental residual (cm), trunk kinematics (°) and breast ROM (cm) relative to each trunk segment, were calculated for the three trunk segments.

Results: Segment capture success varied from 88 % to 100 % depending on the marker set. Segment origin instability ranged from 1.5 cm to 0.2 cm, which represented up to 35 % of superio-inferior breast ROM. Maximum trunk extension differed by 7° depending upon the marker set used and finally breast ROM varied by 41 % in the anterioposterior (A-P), 54 % in the mediolateral (M-L), and 21 % in the superioinferior (S-I) direction (Table).

Figure:

Figure: Marker locations on the trunk segment used to define the trunk reference frames
(Trunk 1 - STN, RRIB, LRIB; Trunk 2 - STN, PX, C7, T8; Trunk 3 - STN, PX, C7, T8, STN33, C750)

Conclusion: Key findings show that Trunk 1 marker set achieved less than 100 % capture success and was also the marker set with the greatest origin instability. Qualitative inspection of optoelectronic data suggests that arm swing during running tended to alternately obscure the rib markers reducing capture success. Furthermore the majority of origin instability occurred in the superioinferior direction, possibly due to motion of the subcutaneous fat at the distal marker locations used for the Trunk 1 segment. Trunk segments with markers restricted to the anterior aspect of the trunk (Trunk 1) caused a backward tilt of the trunk segment relative to the global vertical axis. Within the local coordinate system of the trunk, this tilt altered the directional distribution of the breast. Trunk 2 marker locations (PX, T8) are obscured by a bra's underband therefore preventing its use when female participants are wearing breast support garments. The Trunk 3 marker set maximises capture success and minimises origin instability whilst also having sufficient markers to avoid obstruction from current bra designs and arm swing mechanics. This trunk marker set is recommended when investigating trunk and breast kinematics using the female cohort during running with and without breast support.

Table:

Marker Set	Segment Capture Success (%)	Origin Instability (cm)	Segment Residual (cm)	Trunk Maximum Tilt (°)	Trunk Maximum Flexion / Extension (°)	Trunk Maximum axial rotation (°)	Breast A-P ROM (cm)	Breast M-L ROM (cm)	Breast S-I ROM (cm)
Trunk 1	88	1.5	0.5	-3.5	-5.8	-13.2	3.9	3.5	4.3
Trunk 2	100	0.2	0.4	-4.1	7.9	-18.5	2.6	1.8	5.2
Trunk 3	100	0.2	0.4	-4.1	8.0	-19.4	2.3	1.6	5.0

PO-0253

CHANGES IN MULTISEGMENT FOOT KINEMATICS AS A FUNCTION OF GAIT SPEED

Victoria Chester [1,*] Jeffrey Grant [1] Usha Kuruganti [1] Gwyneth de Vries [2]

[1]Kinesiology, University of New Brunswick, [2]Orthopaedics, Horizon Health, Fredericton, Canada

Introduction and Objectives: The majority of gait research has modeled the foot as a single rigid segment with few degrees of freedom. Recently, there has been an increase in the number of studies using multisegment foot models to examine motion between segments of the foot. While it is known that walking speed influences ankle kinematics derived from simplistic foot models [1-3], relatively little is known about the effects of walking speed on multisegment kinematics. During pathological gait, individuals may walk slower or faster than typical walking speeds. As a result, speed-mediated effects may be difficult to distinguish from those due to an injury, disease and/or disorder. A greater appreciation of the effects of walking speed on multisegment foot kinematics in control groups is needed. Therefore, the purpose of the present study was to examine differences in multisegment foot kinematics as a function of walking speed using healthy controls.

Methods: Twenty-two (n=22) adult participants (11 male, 11 female) were recruited between the ages of 18-30 years (age=23.0±2.6 yrs; height: 1.73±0.1 m; weight: 72.1±10.1 kg). A 12 camera T160 Vicon motion capture system (Oxford Metrics Group, Oxford, UK), sampling at 100 Hz, was used to track the three-dimensional trajectories of 32 reflective markers placed on the participant's skin. Six force plates (Kistler Instruments, Winterhur, Switzerland), embedded in the lab floor, were used to aid in the identification of gait cycle events. The foot model consisted of the 6 rigid segments, including the tibia, hindfoot, midfoot, forefoot, hallux, and total foot. A static capture of the participant during was recorded to permit the calculation of offset values for all joint rotations. Joint offset values were subtracted from the gait cycles of each participant. Planar angles were calculated and reported without any offsets. Participants were asked to perform at least 6 gait trials for the left and right limbs. Displacement data were filtered using a zero phase lag, second order Butterworth filter with a cutoff frequency of 6-9Hz. Relative joint angles were computed using Euler angles. Joint angle data were normalized to 100% of the gait cycle. Gait speed was rendered dimensionless in accordance with Hof [4]. Repeated measures ANOVAs were used to test for significant differences in the mean values of the temporal-spatial values and peak joint angles across 5 walking speeds (very slow, slow, typical, fast,and very fast, Table 1). Data was analyzed using custom software created in Matlab (Mathworks, Inc. Natick, MA, USA).

Results: Significant differences ($p<0.002$) were found in the mean values of temporal-spatial gait variables across gait speeds. Variation in walking speed significantly ($p<0.002$) affected the magnitude and timing of the relative and absolute angles of the foot. All significant changes in the magnitude of angles occurred in the sagittal plane only. Changes in speed altered the angular kinematics of the calcaneus vs tibia, midfoot vs calcaneus, and forefoot vs calacaneus (Figure 1). In addition, planar angles of the hallux, metatarsals, and medial longitudinal arch also varied with speed.

Figure:

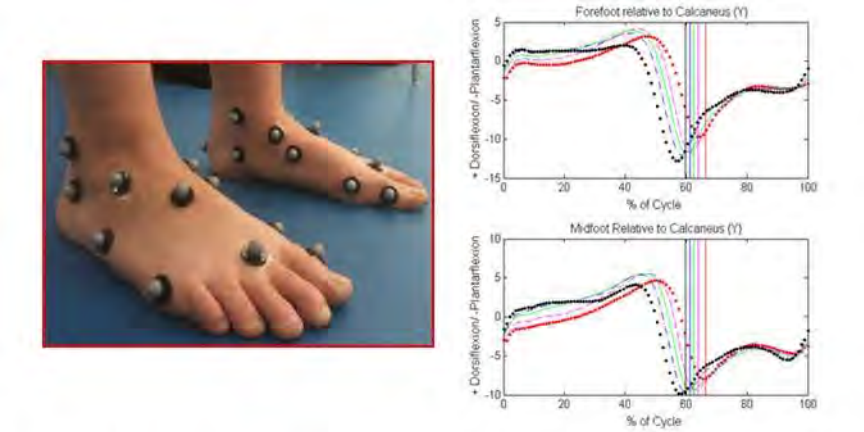

Figure 1: a) Picture of multisegment marker system, b) Example of changes in multisegment angles as a function of speed (black = very fast; red = very slow)

Conclusion: Similar to the single rigid body model, walking speed was found to affect multisegment foot kinematics. These results have important implications for studies examining foot and ankle function in typical and atypical populations. The results suggest that speed-matched control data should be used for the analysis of multisegment kinematics, especially in clinical populations where walking speed is altered by pathology. Such data will also facilitate a greater understanding of gait deviations and the effects of treatment interventions. Future studies should examine the effects of walking speed on multisegment foot kinematics in varying age groups and clinical populations. In addition, changes in multisegment foot kinematics as a function of speed may be further understood through the examination of kinetic, EMG, and plantar pressure data.

Table:

Speed Groups	Dimensionless Speed	Number of Trials
Very Slow	v <= 0.382	43
Slow	0.382 < v <= 0.495	41
Free	0.495 < v <= 0.581	42
Fast	0.581 < v <= 0.721	43
Very Fast	v >0.721	39

PO-0254

AGE-RELATED DIFFERENCES IN UPPER EXTREMITY MOVEMENTS DURING ACTIVITIES OF DAILY LIVING

Victoria Chester [1,*] Brian Beaudette [1]

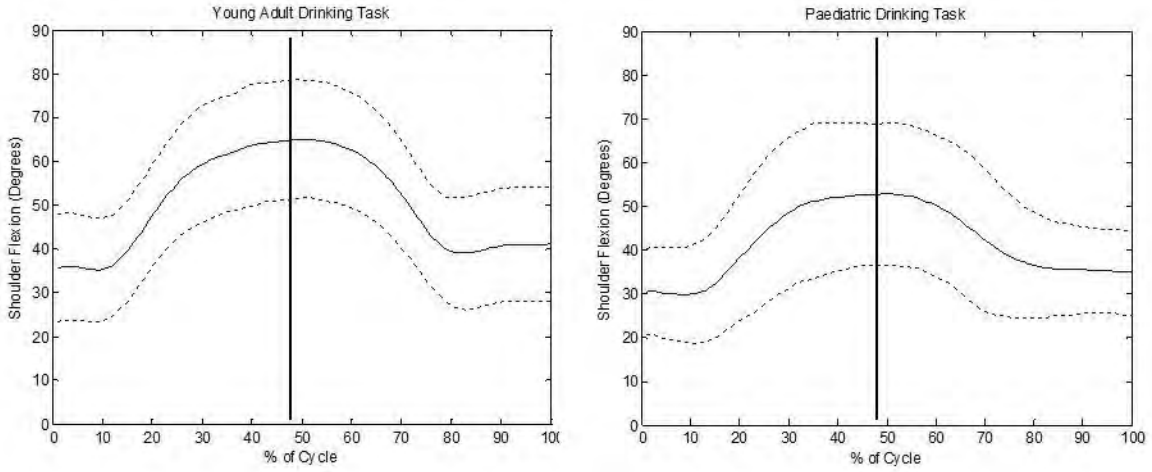
[1]Kinesiology, University of New Brunswick, Fredericton, Canada

Introduction and Objectives: While gait patterns have been studied extensively across the life span, few researchers have examined age-related differences in upper extremity (UE) kinematics during activities of daily living (ADLs) [1-3]. The movement of the upper extremities is a critical component of many ADLs, such as feeding, drinking, dressing and perineal care. Knowledge of changes in UE movement patterns as a function of age is needed to establish valid control databases for the identification of movement deviations in clinical populations (e.g., cerebral palsy). Therefore, the present study examines age-related differences in three-dimensional UE kinematics between young adult and pediatric groups while performing drinking and eating tasks.

Methods: Fifteen young adults (5 male, 10 female), aged 18-24 years (mean age: 20.2 years), and fifteen paediatric participants (5 male, 10 female) aged 7-9 years (mean age: 8.3 years) participated in the study. An eight-camera Vicon MX motion capture system (Oxford Metrics Ltd., UK) was employed to track the three-dimensional trajectories of eighteen (n=18) reflective markers placed on the participants' skin at a sampling frequency of 60 Hz. Rigid body segments included the head, trunk, and the left and right upper arm, forearm, and hand. Each participant was asked to perform a standardized eating task, which involved scooping pudding from a bowl with a spoon, and drinking task, which involved drinking water from a cup. The participants performed the drinking task using both the dominant and non-dominant arms. Joint angles were then computed from the relative orientations of embedded coordinate systems using Euler angles. Two-way ANOVAs were used to test for significant ($p<0.05$) differences in mean maximum joint angle data across age groups and dominant/non-dominant arms.

Results: Significant differences ($p < 0.004$) in mean maximum values of joint angle parameters were found between age groups for both tasks. No significant interactions or differences in mean maximum joint angle parameters were found between the dominant and non-dominant arms. No significant differences in temporal-spatial data were found for the tasks. The young adult had a significantly larger mean maximum elbow flexion than the paediatric group during phase 1 of the eating task (lift spoon to mouth). The young adult group also had a significantly larger mean maximum elbow flexion angle than the paediatric group during phase 2 of the eating task (return spoon from mouth to bowl). The paediatric group showed significantly greater shoulder abduction throughout the task. Both groups showed similar movement variability; however, the young adult group showed more consistent elbow flexion patterns. For the drinking task, the paediatric group had significantly larger mean maximum angles for neck flexion in phases 1 (period between grasping of the cup to the peak of cup sipping) and phase 2 (the period following peak cup sipping to the return of the cup to the table). In addition, the paediatric group had significantly larger mean maximum shoulder abduction in phase 2 compared to those for the young adult group. Significantly lower mean maximum shoulder flexion angles were also found during phase 2 in the paediatric group (see Figure). While the variability of movement was very similar across age groups, the young adult group had consistently lower variability.

Figure:



Conclusion: The results of this study suggest that age-related differences exist in movement patterns between pediatric and young adult age groups during the performance of ADLs. Differences in experience with the task, anthropometrics, techniques used to complete the task, and neuromaturational levels likely contributed to the varying movement patterns. Information on age-related differences in UE kinematics is critical to our understanding of typical movement patterns and future clinical studies involving the UE. The identification of movement deviations and their underlying causes in clinical populations is dependent on the availability of well-defined control data. Differences in UE kinematics between pediatric and young adult age groups demonstrates the importance of using age-matched control groups in future clinical studies. Future work will focus on increasing sample sizes and examining additional age divisions for comparative purposes.

THE EFFECT OF SPRING RESISTANCE AND KNEE SUPPORT ON SHOULDER MECHANICS DURING THE LONG STRETCH EXERCISE ON THE REFORMER IN PILATES

Heiliane D. B. Fontana [1,*] Ana Paula Moratelli Prado [1] Caroline Ruschel [1] Helio Roesler [1]

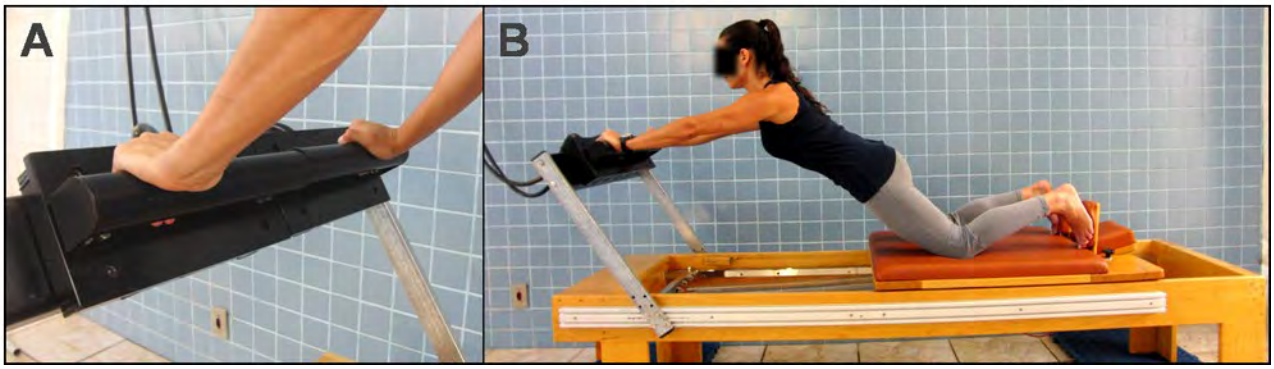
[1] Health and Sports Science Center, University of the State of Santa Catarina, Florianópolis, Brazil

Introduction and Objectives: Among Pilates equipments, the most frequently used is the reformer, which employs spring tension exerted on a movable carriage. Typically, exercise progression on the reformer can be easily made by increasing spring resistance. However, in some exercises, such as the long stretch, resistance will also depend on the subjects body weight and gravity, partly resembling the floor work resistance in Pilates. Despite the frequent use of the long stretch exercise in clinical practice and the increasing popularity of Pilates, the effect of different body alignment and spring resistance on shoulder mechanics remains unknown. The interaction of gravity result in a complex relationship between spring resistance and exercise demand, which challenges the perception of the instructor and patient in order to achieve a proper exercise progression. Therefore, the aim of this study was to analyze the effect of spring resistance and knee support on the shoulder range of motion and torque during the long stretch exercise on the reformer. In this experiment, we chose to evaluate the initial and final position of each movement cycle, as they represent the minimum and maximum spring resistance imposed to the exercise.

Methods: A certified Pilates instructor with seven years of practice (29 years, 50.8 kg and 1.60 m) was invited to take part in the experiment. The subject performed five repetitions of the long stretch exercise in six onditions based on different spring resistances - no spring; one spring (linear resistance R^2>0.99, K=255.65 N/m) and two springs - with and without knee support. In order to collect force data, a recently developed instrumented reformer was used (Figure 1). It contains two specially designed three-axial force plates in parallel (150 x 300 mm each) [1], connected to an acquisition system (ADS2000-IP, Lynx LTDA). All executions were recorded by a synchronized camera (EX-FH20, Casio) placed 3.0 m from the left shoulder sagital plane. Markers were placed at the following anatomical landmarks: ulnar styloid process, acromion, and great trochanter. Images were processed using Kinovea 8.15. From the segment angle of the upper limb and the vertical and antero-posterior forces measured at the reformer instrumented bar, radial and tangential forces to the upper limb were calculated on the sagital plane for both the initial and final position. Tangential forces were multiplied by the upper limb length (0.46 m) to obtain an estimate of shoulder torque on the sagital plane.

Results: In Table 1, the mean values of the analyzed variables are shown. Shoulder net torque varied from 17.6 Nm towards flexion to 50.3 Nm towards extension. At the initial position, shoulder net torque was always directed towards flexion, being negligible when the exercise was performed with knee support, but, similarly to the compressive radial forces, increasing with increasing spring resistance and in the absence of knee support. At the final position, however, all conditions, apart from the two-spring with knee support, resulted in a extensor torque effort, which decreased with increasing spring resistance and with knee support. Shoulder range of motion decreased with increasing spring resistance in the knee support condition; while an opposite trend was observed for the no knee support condition. The changes in range of motion were mainly due to differences in shoulder angle at the final position.

Figure:



Caption: A. Upper limb position on the reformer instrumented bar. B. Long stretch exercise on the reformer.

Conclusion: The relationship between spring resistance, gravity and shoulder mechanics is complex and the common sense that the long stretch exercise is mainly directed to shoulder flexors is misleading. In fact, from the zero to the two-spring condition, the addition of springs provides assistance to shoulder extensors rather than resistance to shoulder flexors, at least in the position in which spring resistance is maximum.

Table:

		WITH KNEE SUPPORT			WITHOUT KNEE SUPPORT		
		NO SPRING	1 SPRING	2 SPRINGS	NO SPRING	1 SPRING	2 SPRINGS
SHOULDER TORQUE(Nm)	INITIAL	-1.1(-1.0)	0.4(1.7)	3.2(0.4)	1.6(-2.0)	7.0(-3.8)	17.7(-7.0)
	FINAL	-39.5(-2.3)	-16.3(2.6)	8.8(8.2)	-50.3(0.6)	-29.8(1.3)	-2.3(2.1)
RADIAL FORCE (N)	INITIAL	39.68(-6.45)	64.59(-13.21)	70.76(-21.59)	162.81(-34.13)	151.04(-32.45)	150.80(-35.18)
	FINAL	-6.87(9.27)	96.06(5.31)	166.35(0.64)	84.46(-38.53)	102.30(-19.04)	171.77(-32.4)
SHOULDER ANGLE (°)	INITIAL	42	51	50	54	55	55
	FINAL	144	140	127	103	130	134
SHOULDER ROM (°)		102	89	77	49	75	79

Caption: Shoulder net torque, radial force, angle and range of motion (ROM) at the initial and final position of the long stretch exercise on the reformer. Data are expressed in mean values and mean absolute difference (in parenthesis) between left and right upper limbs. Mean positive torque and radial force are in the direction of shoulder flexion and compression respectively. Positive absolute differences (in parenthesis) indicate higher forces on the right upper limb.

NORMAL RUNNING GAIT PATTERNS EXAMINED BY HIERARCHICAL CLUSTER ANALYSIS

Angkoon Phinyomark [1,*] Sean Osis [1] Blayne Hettinga [1] Reed Ferber [1]

[1] Faculty of Kinesiology, University of Calgary, Calgary, Canada

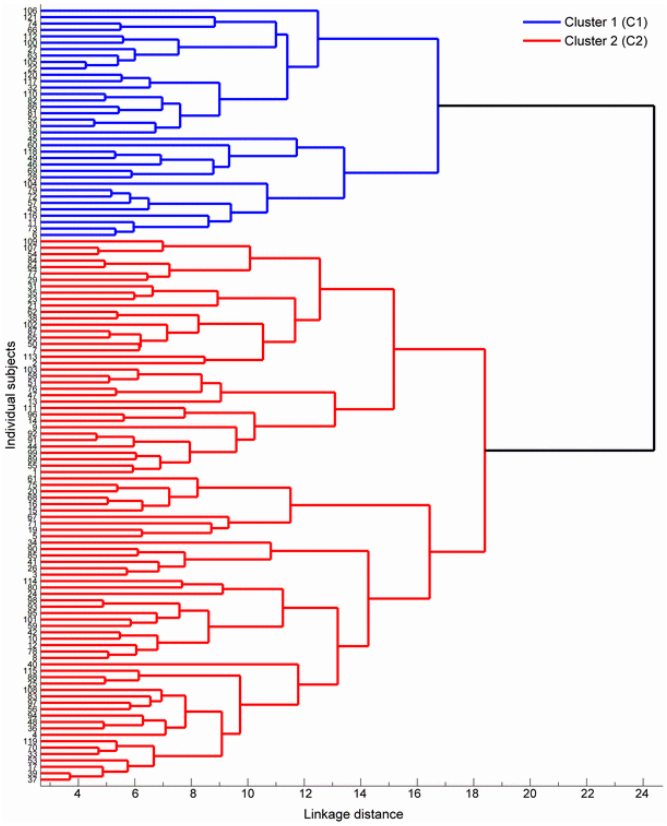
Introduction and Objectives: Previous studies have demonstrated distinct clusters of walking gait patterns in both healthy and pathological groups, suggesting that within samples of walkers, different movement strategies may be represented [1-2], and comparative outcomes may be influenced by these strategies [3]. However, no studies have investigated whether distinct clusters exist for gait patterns in running. Therefore, the first purpose of this study was to determine if running gait patterns for healthy subjects could be classified into homogenous subgroups. The second purpose was to identify differences in joint kinematics between these groups, and then to investigate the practical implications of clustering healthy subjects by comparing these kinematics with runners experiencing patellofemoral pain (PFP).

Methods: Three-dimensional kinematic data from ankle, knee, and hip joints in 121 healthy runners (40 males, 81 females, age 39.45 ± 12.61 years) and 56 PFP runners (20 males, 36 females, age 31.43 ± 8.66 years) were collected in frontal, transverse, and sagittal planes of motion. A principal component analysis (PCA) was used to reduce the dimensionality of the entire gait waveform data from both stance and swing phases of running gait cycle, and then a hierarchical cluster analysis (HCA) determined group sets of similar gait patterns and homogenous clusters based on the Euclidean distance and the Ward's linkage method. The optimal number of clusters was determined using the inflection point on a plot of agglomeration coefficient as a function of cluster number and was confirmed by verifying the consistency and inspecting the dendrogram. Differences in running kinematics between clustering healthy subjects and runners with PFPS were examined based on PC scores and gait waveforms using the analysis of variance and effect size d.

Results: The first 4 PCs, which explained 87.86-96.12% of the total variance in the original data, were retained for each of the waveforms, such that the 36 PC scores (4 PCs x 3 planes x 3 joints) comprised the columns and the 121 subjects comprised the rows of the input matrix for the HCA approach. Two distinct running gait patterns: Cluster 1 (C1) with 36 subjects and Cluster 2 (C2) with 85 subjects were found using the HCA approach, as shown in the Figure, and no significant differences were found between clusters with respect to age, height, weight and running speed ($p > 0.05$). Seven out of the 36 PC scores demonstrated significant differences between the two clusters ($p < 0.05$, $d > 0.8$). Specifically, differences between the clusters in frontal and sagittal plane knee angles were found in PCs 1 and 3 (75.79% of total variance in the data) and PC 2 (23.52% of total variance in the data), respectively. C1 exhibited greater knee abduction angles during 14-35% and 76-96% of running gait cycle compared to C2 and in the sagittal plane knee joint, C1 exhibited greater knee flexion angles during 76-88% of running gait cycle and reduced knee flexion angles during 39-58% and 97-100% of running gait cycle in comparison to C2. Other significant differences between C1 and C2 were present, but explained less than 20% of the total variance, including transverse and sagittal plane ankle joint, transverse plane knee joint, and frontal and sagittal plane hip joint kinematics. Conversely, no differences were found for frontal plane ankle and transverse plane hip joint kinematics.

When these two groups were compared to runners experiencing PFP, one cluster exhibited greater (-7.97º vs -5.49º, p = 0.03; d = 0.49) while the other exhibited reduced peak knee abduction angles (-4.44º vs -5.49º, p = 0.02; d = 0.40). In contrast, no differences in peak knee abduction angles were found for all 121 healthy runners as compared to PFP (-6.04º vs -5.49º, p = 0.43; d = 0.13).

Figure:



Caption: Ward's minimum variance linkage dendrogram of the hierarchical cluster analysis of the normal running gait patterns representing the two-cluster solution. Two groups are highlighted by blue color for Cluster 1 (C1) and red color for Cluster 2 (C2). Participant numbers are indicated.

Conclusion: This is the first study to experimentally demonstrate that the homogeneity of running gait patterns in a pain-free control group could significantly influence the results of a clinical investigation. The variability observed in running patterns across a sample could be the result of different gait strategies. Therefore, it is possible that movement strategies included within a traditional "control" group may influence any biomechanical differences found. These results suggest care must be taken when selecting samples of subjects in the investigation of gait pathomechanics and the biomechanical aetiology of running injuries.

TRAJECTORY BASED ANALYSIS, A NEW METHOD FOR MOTION ANALYSIS USING THE KINECT™ SENSOR

Victor Sholukha [1,*] Bruno Bonnechère [1] Serge Van Sint Jan [1]

[1] LABO, ULB, Brussels, Belgium

Introduction and Objectives: Lots of studies have been done in order to validate Kinect™ sensor as a Markerless System (MLS) for various uses (e.g. motion analysis, posture analysis…) [1,2,3]. Interesting results have been found in term of accuracy (compared to gold standard Marker-Based System (MBS)) and especially in term in precision. Due to the information provided by the Kinect SDK (a simple skeleton model composed by 20 points) it is not possible to directly obtain three-dimensional joint orientation position [4]. Another issue related to motion analysis is the different conventions used (e.g. Euler's sequences) making comparison and interpretation of the results difficult. The objective of this paper was developing advanced (PiG like) MLS model [5] and a new method for motion analysis based on joint trajectories instead of joint angles. Results of this new method are more easy to interpret and could therefore be used in clinics to assess patients status and monitor follow up.

Methods: Twenty healthy adults (26±8 years old, 173±8 cm height, 70±11 kg weight, 23±3 kg/m² BMI, 8 women) were recruited to participate to this study. MLS (Kinect™) and MBS (Vicon™) simultaneously captured motion data from in total 97 trials (per ten repetitions each type of motion) were processed. Four different type of test motion were selected for method testing: squat motion; right hip and shoulder abductions; right elbow flexion.

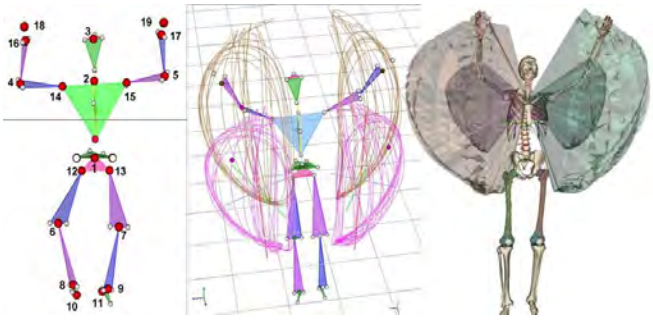
Each frame of the MLS motion data was available as 3D coordinates of crude approximation of the main human joints, e.g. presented in Figure by 20 red circles reconstructed by Kinect™ SDK. The major lack of this approach is the inability of allowing anatomically correct descriptions of the joint angular motion according to today clinical conventions.

To amend this stick-based model we improved the standard linear model to obtain a final model including three points for each segment link depicted in Figure. The new model architecture therefore allows proper anatomical and clinical motion representations. The final enriched model is similar to current standards in clinical motion analysis (such as the Vicon™ PiG model). In total 19 local coordinate systems (LCS), following ISB recommendations for axis orientation, were located in the origins indicated by numbers (1-19) in Figure. Then 33 LCS origin trajectories relative to parent LCS were evaluated. Each of 33 trajectory plots was processed to assess different properties of the shape created by hodograph and also processed (as a point clouds) to assess principal and supplementary axes origin and orientation in parent LCS (see Table for parameter list).

Results: All source motion data were processed and statistic was evaluated for each type of four motions. In total 30 parameters were collected and saved for each of 33 trajectories of processed 97 trials for MLS and MBS captured data. Then for each type of four trials mean and SD value of each of 30*33 parameters were assessed. These parameters could be used for motion analysis and scoring. Most of the parameters show SD variability within 10-20% from mean value.

Finally, absolute and relative difference between correspondent MLS and MBS parameters were evaluated. Mean relative error deviates from 1 to 22%. The best similarity show hip and elbow flexions and shoulder abduction. Hip abduction shows lager difference mainly due to bigger error of pelvis point recognition by MLS when pelvis rotates in frontal plane.

Figure:



Conclusion: Two major results were presented in this paper. First is method for development an advanced model from crude MLS data to get full 3D motion data similar to Vicon™ PiG like protocol. Second, we suggested an alternative way of motion kinematics representation by mainly analysis trajectories of the selected points.

THE COORDINATION MODE ANALYSIS DURING WALKING FORWARD AND BACKWARD

Luis Mochizuki [1,*] Karine Külkamp de Souza [2] Vanessa Herber [2] Fernanda Romaguera [2] Stella Maris Michaelsen [2]

[1]Physical activity sciences, Universidade de São Paulo, São Paulo, [2]Physioterapy, Centro de Educação Física, Fisioterapia e Saúde, Universidade do Estado de Santa Catarina, Florianopolis, Brazil

Introduction and Objectives: The information about how joints are coordinated is provided by several methods which tell about the similarity in the time, frequency or space domain of the data. During a motor task, there is a very simple and important question: what movement joint B performed when joint A was moving? This information is necessary to understand the risk for injury. The aim of this study is to describe how to perform coordination mode analysis (CMA) e discuss the importance of this novel analysis to understand the motor coordination during gait analysis.

Methods: Eight healthy adults participated in this study. One camera (HSC 180, 30 Hz frequency sampling) were used to shut the task. For the image digitalization, it was used the Ariel Performance Analysis System, APAS 1.4. The body markers were placed on acromion, greater trochanter, lateral condyle of tibia, and lateral malleolus of fibula. The participant walked forward and backward freely a treadmill at its self-selected speed. The hip and knee angles were calculated for the sagittal plane. The time series of those angles was low-pass filtered (2th order Butterworth, 20 Hz) and smoothed with quintic spline function. The coordination modes analysis (CMA) is based on the modified vector coding analysis [1] and the calculation of the inclination angle f of vector defined by a pair of consecutive points (a_i, b_i) and (a_{i+1}, b_{i+1}). Then, the time series of the coupling angles is codified with numbers (1 inphase, 2 antiphase, 3 a phase, and 4 b phase) which represents each coordination mode, this is the coordination mode sequence (COMOS). The COMOS is a m x 2 matrix, where m coordination modes and their relative times are provided. The COMOS variability is quantified by the CMS polymorphism, considering the variability within each COMOS and among COMOS. The variability along the positions is the polimorphism of the coordination. The polymorphism on each site of n COMOS is calculated by the heterozygosity h at the site i and the relative frequency of each coordination mode c_{ij} (j=1,2,3,4).

$h_i=n(1-\Sigma c_{ij}^2)/(n-1)$

The heterozigosity is calculated for COMOS of the same size. The COMOS of same size are called as codon# and # identifies how many coordination modes exist in that codon#. For example, codon2 is a COMOS with two coordination modes. The structure of the codon# reveals the coordination strategy applied to perform the task. The set of diferent codon# builts the motor coordination codex index (MOCX), the descriptor of the motor coordination strategy. Other information provided by the COMOS is how a coordination mode shifts to another. There are three type of coordination mode transition (COMOTA): a) inversion: from inphase to antiphase or from antiphase to inphase, from phase a to phase b, or from phase b to phase a; b) restriction: from inphase or antiphase to phase a or phase b; c) synchronization: from phase a or phase b to inphase or antiphase.

Results: The amount of coordination modes was affected by walking ($H=5.4$ $p=0.01$). Walking forward presented more coordination modes than walking backward ($p<0.05$). The inphase ($H=1.4$ $p=0.22$) and antiphase ($H=2.6$ $p=0.10$) modes were not affected by the type of walking. The knee phase ($H=18.7$ $p<0.001$) and hip phase ($H=5.5$ $p=0.01$) modes were

affected by walking. Walking forward presented the highest quantity of knee phase mode during the gait cycle. The type of walking affected the quantity of invertions (H=3.9 p=0.04), but the amount of synchronizations (H=3.7 p=0.05) and restrictions (H=3.4 p=0.06), during the gait cycle. From the codon2 to codon9, the mean *h* indexes calculated for walking forward and backward were similar. From codon10 to condon13, the diference between walking forward *h* indexes increases because the variability of the coordination modes decreases in walking backward.

Conclusion: The CMA is a novel method to describe the coordination between two joints. We showed how the hip and knee are coordinated during walking forward and backward. It provides information about the coordination rules and it is potential tool to describe how two joints move together.

Table:

Coordination mode	Walking type	Quantity of coordination modes (median [25%,75%])				
		Gait cycle	Stance			Swing
			Early	Middle	Late	
Phase	Backward	3 [2,3]	1 [1,1]	0 [0,0]	1 [0,1]	1 [1,1]
	Forward	3 [3,3]	0 [0,0]	1 [1,1]	0 [0,0]	2 [1,2]
Antiphase	Backward	3 [3,3]	1 [1,1]	1 [1,1]	0 [0,0]	1 [1,1]
	Forward	3 [3,3]	1 [1,1]	1 [0,1]	0 [0,0.75]	1 [1,1]
Knee	Backward	2 [2,3]	0 [0,1]	0 [0,1]	1 [0,1]	1 [1,1]
	Forward	3 [3,3]	1 [0,1]	0 [0,0]	1 [1,1]	1 [1,1]
Hip	Backward	3 [3,3]	1 [1,1]	1 [1,1]	0 [0,0]	1 [1,1]
	Forward	3 [3,3]	1 [1,1]	1 [1,1]	0 [0,0]	1 [1,1]

THE EFFECT OF TRUNK OVERWEIGHT IN GAIT BIOMECHANICS DURING PREGNANCY

Liliana Aguiar [1,*] Rita Santos-Rocha [2] Filomena Vieira [3] Marco Branco [2] Andrade Carlos [1] António Veloso [1]

[1]Faculty of Human Kinetics, University of Lisbon, Oeiras, [2]Sport Sciences School of Rio Maior , Polytechnic Institute of Santarém , Santarém, [3]Faculty of Human Kinetics, Polytechnic Institute of Santarém, Oeiras, Portugal

Introduction and Objectives: The main purpose of this study was to understand the effect of the increased mass in the trunk associated to gait during pregnancy, on joint range of movement (ROM) and moments of force (M_f), by comparing three loading conditions: 2nd trimester pregnant women (PG); non-pregnant women (NPG); non-pregnant women carrying an additional load of 5 kg placed in the abdomen and breasts.

Methods: The PG walked during non consecutive three minutes. The NPG performed two trials of gait at a self-selected speed, one of them carrying 5 kg extra load. This value was calculated based on IOM recommendations for weight gain during pregnancy [1,2], which was 0.42 kg/week, and its distribution was 46% located in the belly and 32% in the upper trunk [3], resulting in 4 kg on the belly and 0.5 kg in each breast for this group (load carrying group, LCG).

Motion capture was performed with an optoelectronic system of twelve cameras Qualisys (Oqus-300) operating at a frame rate of 200Hz, synchronized with two force platforms (Kistler AG, Winterthur, Switzerland) and one AMTI (Advanced Mechanical Technology, Inc, Watertown, MA), which collected ground reaction force data.

To reduce the effect of soft tissue artifact, a global optimization on the data processing algorithm was performed [4]. The model also assumed a universal joint to the ankle, a revolute joint to the knee and a spherical joint to the hip.

The inverse dynamics method was used to estimate net M_f produced by the muscular action. To calculate ankle, knee and hip ROM and M_f, the 3D biomechanical models were constructed, using the software Visual 3D C-Motion, Inc.

Results: The average joint angles and moment curves were obtained for each participant as well as the mean curve for the three groups.

Caption: Figure 1- Ankle, knee and hip joints and pelvis range of motion (ROM) in sagittal (first row), frontal (second row) and transversal planes (third row) for the non-pregnancy (NPG), pregnancy (PG) and load carrying (LCG) groups.

Conclusion: A set of variables is defined when there are significant differences in a variable in (NPG_PG) and (NPG_LCG), and no difference in (PG_LCG), which has a clear relation with the trunk weight.

Thus, we find the variables: maximum hip extension, maximum pelvic right obliquity, pelvic obliquity ROM, maximum transversal left rotation and peak hip flexion Mf. The trunk weight gain increases both stance phase duration and DLST in both LCG and PG subjects. The body's response to the external hip flexor M_f is related to a higher extensor activity to support the anterior additional mass of the trunk and to the forward translation of the center or mass. The pelvis amplitude on the frontal and transversal planes, may be reduced due to the surrounding constraints, once it supports the belly weight. The hip joint and pelvis are adjacent to the trunk and can be more affected by the weight gain and its distribution.

The relation between anterior trunk extra weight and gait modifications needs further research since weight gain during pregnancy provides higher biomechanical joint loads during walking that can cause injuries by overuse of certain specific muscles.

A COMPARISON OF METHODS TO ESTIMATE FOOTSTRIKE, TOE-OFF AND CONTACT TIME USING KINEMATIC DATA DURING OVERGROUND RUNNING

Laura C. Smith [1] Stephen Preece [1,*] Duncan Mason [1] Christopher Bramah [1]

[1] School of Health Sciences, University of Salford, Salford, United Kingdom

Introduction and Objectives: The gait cycle is frequently divided into stance and swing phase; identification is reliant upon accurate detection of the gait events footstrike and toe-off. This is typically achieved using force plates, however in some situations force plates cannot be used [1], it is therefore necessary to use kinematic algorithms to estimate events. Published algorithms for detecting gait events during running are based around timing of kinematic events, such as minimum shank and foot angular accelerations [2]. Although relatively good estimation accuracy of algorithms has been reported [1,2], some algorithms fail to accurately determine the timing of footstrike [3], alternatively have not been shown to estimate gait events as accurately when implemented in subsequent studies [1,2]. Furthermore, previous research has not reported associated errors in contact times [1,3,4] and has only tested algorithms at relatively slow speeds [1]. It is therefore unknown how published algorithms perform at higher speeds, characteristic of competitive races. The aim of this study was to propose a new custom-designed kinematic algorithm and compare its accuracy with established algorithms for footstrike, toe-off and contact time estimation at a relatively fast running speed.

Methods: Twenty elite runners (16 male and 4 female; age 24.3±4.4 years, mass 63.3±8.5 kg and height 177.3±6.8 cm) ran along a 35 m track at 5.6 m/s (±2.5%), contacting an AMTI force plate (1200 Hz) with their right foot. Synchronised three-dimensional kinematic data (240 Hz) were collected using a twelve-camera motion capture system (ProReflex, Qualisys). Kinematic data were filtered with a fourth order Butterworth low pass filter with a cut-off frequency of 10 Hz. Segmental kinematics were derived using a global optimisation approach [5]. Ground reaction forces determined true footstrike (>20N) and toe-off (<20N) events. Four existing algorithms (detailed in [1]) and one custom-designed algorithm were implemented to estimate footstrike and toe-off. The custom-designed algorithm estimated footstrike at the first maximum in vertical displacement between the heel and PSIS marker (Fig. 1a) and toe-off at the maximum vertical displacement between the second metatarsal head and PSIS marker, which was closest to the second peak knee extension (Fig. 1b). Errors for each algorithm were calculated as True Error (TE) (mathematical difference between estimated and true gait event time) and Root Mean Square (RMS) error. Differences between true and algorithm contact times were examined in SPSS 20 using repeated-measures ANOVA, with Bonferonni post hoc analysis ($p \leq .05$).

Results: The results show there were differences in accuracy between algorithms (Table 1). The custom-designed algorithm (Smith) provided the most accurate estimation of footstrike, demonstrating the lowest TE (1.2±17.1 ms) and RMS errors (14.1 ms). The Alton algorithm most accurately estimated toe-off (TE -3.8±4.2 ms and RMS 6.1 ms), however this was only marginally better than the custom-designed algorithm (TE 4.7±5.9 ms and RMS 9.2 ms). The custom-designed algorithm produced the most accurate estimate of contact time which was not significantly different to true contact time ($P > .05$). All other algorithms were significantly different to true contact time.

Figure:

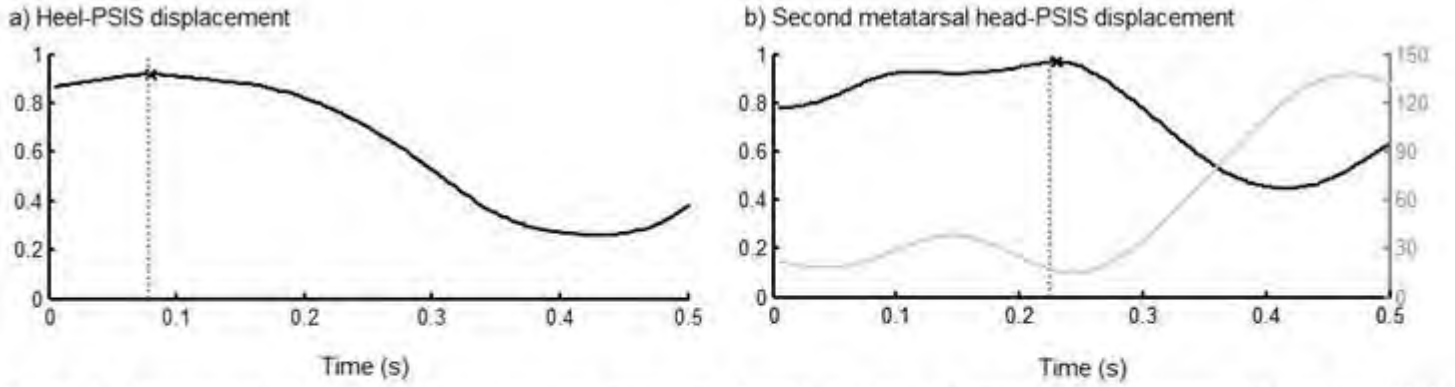

Figure 1. Representation of the custom-designed algorithm (Smith). a) Vertical displacement between the heel and PSIS marker is plotted against time and footstrike estimated to occur at the first maximum (denoted with an **x**). The dashed line shows footstrike time derived from the vGRF. b) Vertical displacement between the second metatarsal head and PSIS marker is plotted against time and toe-off estimated to occur at the local maxima closest to the second peak in knee extension. This estimate is marked on the graph with an **x**, in which the black line represents the custom-designed algorithm, whereas the grey line represents knee flexion-extension and again the dashed line represents vGRF derived toe-off.

Conclusion: There were differences in accuracy between the algorithms. The results showed the accuracy of contact time estimation varied between different algorithms, due to a combination of under and over estimations in footstrike and toe-off. The results illustrate that compared to the other tested algorithms, the custom-designed algorithm provided an accurate estimation of footstrike, toe-off and contact time; therefore provides a simple but effective method to accurately estimate footstrike, toe-off and contact time from kinematic data. In instances whereby ground reaction force data is not available we would recommend the use of the new algorithm for estimating gait events from kinematic data at faster speeds; however further work is required to confirm whether it would be equally effective at slower speeds.

Table:

		Smith	Alton	Dingwell	Hreljac	Zeni
Footstrike	TE	1.2±17.1	32.0±14.1	-27.4±7.4	-20.0±8.6	18.7±81.4
	RMS Error	14.1	32.3	27.9	23.1	151.7
Toe-off	TE	4.7±5.9	-3.8±4.2	13.8±10.5	34.1±50.7	91.4±22.5
	RMS Error	9.2	6.1	19.7	66.6	106.4
Contact	Contact Time	171.1±21.6	131.8±19.8*	208.7±13.4*	221.7±50.8*	240.3±81.0*
	TE	3.5±18.2	-35.8±16.0	41.1±10.8	54.1±48.8	72.7±78.0
	RMS Error	18.4	36.8	44.6	74.1	202.0

Caption: Table 1. Mean±SD Error between estimated and true gait events (in ms).Positive and negative values indicate algorithm overestimation and underestimation respectively. * denotes algorithm contact time is significantly different ($p < 0.05$) to true contact time (167.6±8.9 ms).

INFLUENCE OF UPHILL WALKING ON SPATIO-TEMPORAL PARAMETERS OF GAIT DURING LOAD CARRIAGE OPERATIONS IN INDIAN SOLDIERS

Anilendu Pramanik [1,*] Deepti Majumdar [1] Bodhisattwa Chowdhury [1] Sohini Paul [1] Tirthankar Chatterjee [1] Madhusudan Pal [1] Dhurjati Majumdar [1]

[1] Ergonomics, Defence Institute of Physiology and Allied Sciences, Delhi, INDIA, Delhi, India

Introduction and Objectives: Soldiers are often expected to carry heavy loads over long distances through undulating and mountainous ranges. They may need to walk uphill with load while maintaining stability of gait at the same time. Though such load carriages on inclined surfaces are frequently encountered in a soldier's everyday life but their effects on the gait is relatively less understood. Treadmill walking has been shown in literature as an appropriate simulation of uphill and downhill locomotion at a common laboratory setup. The present study hypothesized that undertaking uphill treadmill walking with military load should result in alteration of gait pattern.

Indian soldiers generally carry loads in existing ensembles (ELCe) comprising of backpacks (BP, 10.7kg), haversack (HS, 4.4kg) on waist, WEBB (2.2 kg) on chest and rifle (4.2kg) in hand or on shoulder, resulting a total load of 21.4 kg. Depending on the operational requirement, either they carry these ensembles in single unit or in combinations.

Methods: Twelve healthy male Indian Infantry soldiers with mean (SD) age 26.8(3.8) yrs, height 170.6(3.3) cm and weight 66.4(6.8) kg, volunteered for the study. They walked on a treadmill at comfortable speed (3.0 km/hr), without load and with carrying 10.7kg (HS, WEBB and Rifle, 16.1% of body weight) and 21.4kg (ELCe, 32.2% body weight) load respectively. Total duration of walk was 30 mins, with every 6 mins each at 0%, 5%, 10%, 15% and 20% positive gradients. Their gait data was collected using 6 Camera based 3D Motion Analysis System. The temporal parameters (total support time, initial double support time, single support time) and spatial parameters (cadence, swing phase) of subjects data have been reported for each condition.

Results: Results shows that cadence decreased with uphill walking while total support time increased and the changes were significant with increasing gradients. These observations indicate that even low magnitude loads (10.7 kg, 21.4 kg) cause significant changes in spatio-temporal parameters of gait while uphill walking.

Conclusion: These changes may be explained as adaptive phenomena to counteract the effects of gradient and load on gait.

BIOMECHANICAL STRATEGIES FOR SUCCESSFUL OBSTACLE-CROSSING IN PATIENTS WITH ANTERIOR CRUCIATE LIGAMENT DEFICIENCY

Horng-Chaung Hsu [1,*] Tung-Wu Lu [2 3] Shih-Wun Hong [1]

[1]Department of Orthopaedics, China Medical University Hospital, Taichung, [2]Institute of Biomedical Engineering, National Taiwan University, [3]Department of Orthopaedic Surgery, School of Medicine, Taipei, Taiwan, Republic of China

Introduction and Objectives: Identification of movement deviations and compensations in patients with anterior cruciate ligament deficiency (ACLD) during daily activities is helpful for the rehabilitation of such patients. Obstacle-crossing is a common motor task in our daily living, requiring both stability of the stance limb and accurate end-point control of the swing limb. Therefore, it can be a great challenge to those with ACLD because both the structural stability and sensory feedback of the ACL are impaired. It remains unclear whether specific strategies exist in such patients in coping with obstacles during gait. The purpose of the current study was to identify the biomechanical strategies adopted by patients with ACLD in crossing obstacles of different heights.

Methods: Twenty unilateral ACLD patients and seventeen healthy subjects were recruited in the current study. Each subject walked and crossed obstacles of heights of 10%, 20% and 30% of their leg lengths at a self-selected pace. Kinematic and kinetic data were measured with a 7-camera motion analysis system (Vicon, Oxford Metrics, U.K.) and two force plates (AMTI, U.S.A.). The leading and trailing toe clearances were calculated as the vertical distances between the toe markers and the obstacle when the toe was directly above the obstacle. Joint angles of both limbs, and joint moments of the trailing limb, were calculated. Peak extensor moments at the knee during stance phase and the corresponding joint angles were extracted for statistical analysis. Two clusters of the ACLD patients were identified by a hierarchical cluster procedure of Ward's method with peak joint moment as a cluster variable. A 3 by 3, 2-way mixed-model analysis of variance with one between-subject factor (group) and one within-subject factor (obstacle height) was performed (α=0.05). SAS version 9.2 was used for all statistical analysis.

Results: The two clusters of the ACLD patients according to the peak knee extensor moments were Group A (N =9) and Group B (N =11). No significant differences in the toe clearances were found between Group B and the control group (Table 1). Significantly reduced leading and trailing toe clearances and peak knee extensor moments on the affected limb were found in Group A when compared with those of the other groups (Table 1). Group A showed significantly reduced knee flexion in the stance limb when peak knee extensor moments occurred.

Conclusion: Two distinctive gait patterns were identified in the ACLD subjects during obstacle crossing. Differentiation of the subtle differences in the strategies adopted by the ACLD population may help improve the efficacy of the rehabilitation efforts in different ACLD subgroups. The ACLD patients with decreased extensor moments of the knee (Group A) appeared to be at a higher risk of stumbling over the obstacle. Advanced rehabilitation program or reconstruction of the ACL is suggested for this subgroup.

Table:

Limb	Variables	Obstacle Height (%)	Group A (N=9)	Group B (N =11)	Control (N =17)
Affected	Leading Toe Clearance (mm)	10	117.35 *	137.28	149.58
		20	99.00 *	145.14	143.25

THE EFFECT OF DIFFERENT LATERAL JUMP SMASH CONDITIONS DURING LANDING PHASE IN BADMINTON

Po-Teng Huang [1,*] Jia-Hao Chang [1]

[1]Physical Education, National Taiwan Normal University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Overhead striking, like lateral jump smash, used to apply in competition of badminton. The footwork training has been used in badminton, but it is no ball strike in this training. To improve the reality in training, the purpose of this study was to understand the lower limb biomechanics between contralateral footwork (CF), contralateral hitting (CH) and contralateral target (CT) lateral jump smash.

Methods: Six male elite badminton players (13 ± 2.2 years training experience, aged; 22.6 ± 2.7 years, height: 177.4 ± 2.8 cm, mass; 72.3 ± 6.2 kg) participated in this study. All the participants were stood in the center of court and performed three times lateral jump smash in three conditions (CF, CH and CT). After landing, participants were quick returned to the center of court. A Vicon motion capture system (ten cameras, 300 Hz) and a Kistler force plate (1500 Hz) were used to collect biomechanics data during the landing phase. Vicon Nexus and Visual3D software were used to analyze kinematic data. All data were compared by using SPSS 22.0 in three conditions. Repeated measures ANOVA was used to test the differences of CF, CH and CT in the initial contact joint angle and maximum range of motion (ROM) ($\alpha = .05$).

Results: CF hip flexion was significantly larger than CH and CT, CT hip flexion was significantly larger than CH and at the initial contact. CF knee ROM was significantly larger than CH, CF ankle ROM was significantly smaller than CH and CT at touchdown to leave floor ($p < .05$).

Conclusion: The footwork training had the different kinematic in landing. The hip flexion increased in initial contact in CF group. The knee ROM increased and ankle ROM decreased in CF group during landing phase. We concluded that training with ball had the different landing kinematic with only footwork training.

Table:

Table1 Mean ± SD (degree) of hip, knee and ankle joint kinematics at initial contact

	CF	CH	CT	p
Hip Flexion(+)/Extension(-)	12.87 ± 4.67	6.09 ± 7.00	11.317 ± 5.13	.001*
Knee Flexion(-)/Extensio(+)	-13.51 ± 3.35	-14.24 ± 3.66	-13.78 ± 3.10	.375
Ankle Dorsiflexion(+)/plantar flexion(-)	-26.76 ± 3.85	-27.76 ± 2.75	-27.39 ± 4.00	.528

*CF > CH, CT; CT > CH

PO-0265

DOES A DIFFERENCE IN THE LOCATION OF WEIGHT IN A BACKPACK AFFECT HUMAN GAIT?

Takashi Nakayama [1,*]Keio Ishiguro [1] [1]Tomokazu Muto [1]

[1]Physiotherapy Department, Tokyo University of Technology, Tokyo, Japan

Introduction and Objectives: Backpacks have varying designs, sizes, and functions, and are currently considered to be very useful for carrying luggage, while dispersing pressure appropriately and maintaining a suitable load on the back, when walking. In the present study, we aimed to assess the effect of weights loaded at different locations in a backpack on human walking on level and sloping surfaces.

Methods: Eleven healthy male volunteers, aged 19 to 22 years, participated in this study. None of the subjects had any impairments in walking due to orthopaedic diseases or conditions of the spine and legs. The aim and method of the study were described to the participants prior to study initiation, and their consent was obtained. The subjects were asked to walk on a flat surface and an ascending slope (6°) without any weight and while wearing weighted backpacks with weights placed randomly at different locations such as the anterior, upper posterior, and lower posterior locations. The loaded weight was set as 15% of the subject's body weight, based on previous reports. While walking, the three-dimensional angular displacements and moments of the hip, knee, and ankle, as well as lateral displacement of the centre of gravity (LDCOG) were obtained using the VICON Nexus system and 4 force plates. The electromyography (EMG) activities of the gluteus medius, rectus femoris, biceps femoris, tibialis anterior, and gastrocnemius were recorded using surface electrodes at a sampling rate of 1000 Hz, and were sequentially processed as %integrated electromyograms (%iEMGs) according to the ratio of the maximum voluntary contraction volume of each muscle.

Results: Compared with no-weight walking, the flexion ranges of motion of the hip and knee as well as the dorsiflexion of the ankle in the sagittal plane and maximal flexion moment during the stance phase when walking on an ascending slope were significantly larger than when walking on a level surface ($p < .05$, table). Although there was no significant difference among the three different loading conditions, the flexion range of the knee during anterior-loaded backpack walking was significantly larger than that during the other two loading conditions. However, no significant difference was noted in the LDCOG, moments, and %iEMG results for the muscles examined among the different loading conditions.

	ankle	101.3 ± 11.4	* 87.8 ± 16.8	−11.2 ± 4.6	−18.1 ± 13.5	112.5 ± 6.9	* 105.9 ± 10.0

Caption: A comparison of angles and moments at the hip, knee and ankle with and without loading backpacks during walking.

Conclusion: The study results suggest that loading of the backpack with weights at different locations (15% of body weight) may not affect the kinematic and kinetic body mechanics during walking. However, larger angular displacements in the lower extremity joints may be needed for the body to move forward when walking with a loaded backpack on an ascending slope. [A2] However, further studies, including assessments of the movement and muscular activity of the trunk under more-specific and precise biomechanical settings may, be needed to clarify the mechanism underlying different gaits when carrying a backpack.

DATA CONSISTENCY ACROSS MULTIPLE GAIT LABORATORIES

Kenton Kaufman [1,*] Emily Miller [1] Trevor Kingsbury [2] Elizabeth Russell Esposito [3] Erik Wolf [4] Jason Wilken [3] Marilynn Wyatt [2]

[1]Orthopedic Surgery, Mayo Clinic, Rochester, MN, [2]Naval Medical Center-San Diego, San Diego, CA, [3]Center for the Intrepid, Brooke Army Medical Center, San Antonio, TX, [4]Walter Reed National Military Medical Center, Bethesda, MD, United States

Introduction and Objectives: Data reliability is of utmost importance when attempting to share data across sites to evaluate patient progress or to pool research data for comparative effectiveness studies. Twelve motion analysis laboratories found an average 15 degree difference for all parameters measured across sites and, between testing days at one site, five of eight parameters measured were significantly different [1]. This study raised concerns about comparing gait data across different laboratories. More recently, it has been demonstrated that it is possible to pool normative data between two gait analysis services [2]. However, the concern about inter-lab reliability still remains. Therefore, the purpose of this study was to evaluate consistency in 3-D gait measurements across three motion analysis laboratories.

Methods: Ten subjects (6 male/4 female, age 30 $\pm$ 6 years, BMI 24 $\pm$ 4 kg/m^2) without any neuro-musculoskeletal impairments were studied after signing an IRB approved consent form. Subjects traveled to the three foremost Department of Defense Medical Treatment Facilities to be studied. The marker set was applied by a single examiner at each site. The marker configuration, camera systems, and examiners differed across sites. Subjects walked at self-selected and Froude (0.16) speeds. Data were collected for five strides per side during a single session, and then this procedure was repeated for three separate sessions at each site. Data were processed with Visual 3D (C-Motion, Germantown, MD) at each site, de-identified, and sent to an independent evaluator for analysis. Inter-trial, inter-session, and inter-lab errors were quantified [3].

Results: It was possible to collect reliable data across labs for Froude walking speeds (see Table 1). Mean kinematics errors were <5 degrees and peak errors were <6 degrees. Mean kinetic data differed by <10% for the hip sagittal and frontal plane, 16% for the knee sagittal plane, and 4% for the ankle sagittal moments. Similar results were obtained for the self-selected walking speed.

Conclusion: This study demonstrates that high quality data can be collected from multiple gait laboratories, even while using different testing methodology. Previous work demonstrates that it is possible to minimize between session variability within a laboratory with quality assurance techniques and training [3]. This study demonstrated that differences in marker placement, marker sets, testers and collection environments between sites did not preclude the collection of consistent data. A key to similarity between sites was use of identical anatomical segment definitions for the respective gait models. Measurement consistency across sites participating in multi-center research studies directly influences required sample size, level of detectable difference, and statistical power.

Table:

		Mean across Gait Cycle			Peak during Gait Cycle		
		Inter-trial	Inter-Session	Inter-lab	Inter-trial	Inter-Session	Inter-lab

INTRA-LIMB COORDINATION AS A VALUABLE PARAMETER TO DISTINGUISH GAIT ALTERATIONS IN DIABETIC INDIVIDUALS: A PRINCIPAL COMPONENT ANALYSIS APPROACH

Liu Yi [1,*] Cristina Sartor [2] Francis Trombini-Souza [2] Isabel Sacco [2]

[1]Federal University of Sao Paulo, Santos, [2]Physical Therapy, Speech and Occupational Therapy, University of Sao Paulo, Sao Paulo, Brazil

Introduction and Objectives: The more typically discussed biomechanical variables used to describe gait alterations in diabetic patients are: the reduced joint motion, mainly at the ankle, and the increased peak plantar pressure, commonly associated to ulcerations. Particularly the kinematic variables are usually interpreted alone, without considering their dynamical links between joints. In addition, some other motor aspects of diabetic gait could be exploit and thus revealed to be altered due to the global and symmetrical nature of the neuromuscular impairments of the diabetic neuropathy (DN). Intra-limb joint coordination during gait can offer valuable information about the changes that the diabetes might produce into the system, but it has seldom been addressed in diabetic population. Our aim is to identify the most representative kinematic and coordinative variables among patients with and without DN to identify how the disease affects the gait cycle. We are also interested in identifying if there would be variables that could distinguish between healthy and different stages of diabetes progression.

Methods: Thirty nine subjects between 45 and 65 years old were analyzed. According to the clinical evaluation of signs and symptoms of DN, the subjects were classified based in the Fuzzy model previously developed [1] into 3 groups: Control Group (CG = 13), Diabetic Group (DG = 13), Diabetic Neuropathic Group (DNG= 13). The Phase Angle for hip, knee and ankle joints during gait cycle were calculated ($\theta_{i} = \tan^{-1} [y_i/x_i]$). Afterwards, the Relative Phase Angle (rpa) was calculated, consisting of a difference between distal and proximal joint Phase Angle ($\theta_{\text{relative phase}} = \Phi \text{ distal segment} - \Phi \text{ proximal segment}$). Principal Components Analysis (PCA), were performed from the data set enrolled by 101 points of the gait cycle x 88 cycles x 9 variables. The variables: (1-2-3) sagittal ankle, hip and knee angular displacements, (4-5-6) sagittal ankle, hip and knee velocities, (7) rpa ankle-hip, (8) rpa ankle-knee, (9) rpa knee-hip were considered. According to Kaiser criteria, a sample of 85 cycles could explain 60% of the variability of the data. In the present study we had 88 cycles per group. Therefore, the sum of the eigenvalues of the first two principal components was set at 70% [2,3]. To compare PCA´s eigenvectors between groups, two-way ANOVAs and Newman-Keuls post-hoc were applied ($p<0.05$).

Results: The variables that represented the largest variance of the gait cycle were: for the DG in the first PC - hip velocity (-0.15) and rpa ankle-hip (0.16); for the DNG in the second PC - rpa ankle-knee (0.15) and ankle velocity (-0.13); for the CG in the second PC – ankle velocity (0.14), rpa ankle-knee (0.17) and rpa knee-hip (-0.13). For PC1, CG was different from DG in the ankle, hip and knee velocities, rpa ankle-hip, rpa ankle-knee. We also found differences for the PC 1 between DG and DNG in the rpa ankle-angle, ankle and knee velocities. For PC2, CG was different from DG in ankle and knee angles, and rpa knee-hip. We found differences between DG and DNG in the rpa knee-hip for the PC 2.

Caption: Mean, standard deviation and Eigenvectors values, in different groups of patients, for PC1 and PC2.

Conclusion: The most representative variables that can explain differences between gait of healthy, diabetic and diabetic neuropathic patients are related to the hip and ankle velocities, and also the coordination pattern between the ankle-hip and ankle-knee. The hip velocity and its coordination coupled with the ankle could be identified in diabetic patients, which still do not have the typical ankle and foot impairments. On the contrary, in the DN group, the coordination between ankle-knee and ankle velocity characterizes more their pattern. Sagittal kinematics of the lower limb is not a good variable to distinguish the studied groups, even in the most severe neuropathic patients. Since our sample was composed by patients that did not had an ulceration history, preventive actions should take into account the altered coordination between lower limbs that have not been described yet in this population. The traditional and expected restriction of joint motion, especially at the ankle, may be more relevant in patients that have major foot comorbidity.

HOW DOES THE TOE STEP AFFECT BIOMECHANICAL CHARACTERISTICS OF LOWER LIMB IN PINNACLE TRAINER STEPPING?

Yu-Lin You [1,*] Yu-Chi Hsu [1] Hsiao-Feng Chieh [1] Chien-Ju Lin [1] Li-Chieh Kuo [2] Fong-Chin Su [1 3]

[1]Biomedical Engineering, [2]Occupational Therapy, [3]Medical Device Innovation Center, National Cheng-Kung University, Tainan, Taiwan, Republic of China

Introduction and Objectives: Exercise with fitness equipment is more popular in the recent years. Some of these fitness equipment acted as a close kinetic chain exercise [1], such as stationary bicycle, elliptical trainer and stair climber. Close kinetic chain exercise was performed as the foot fixed and knee motion is accompanied by motion at the hip and ankle [2]. This kind of exercise produced greater compression force and a greater antero-posterior force on knee compared with the open kinetic chain exercises [2]. In our previous study, we found participants stepped the pinnacle trainer (S770, SportsArt Fitness, Taiwan) at their comfortable and faster than comfortable speed appeared toe step movement during stepping at the terminal stepping phase rather than heel toe step together. Stepping the pedal with the toe only may involve more ankle strategy during stepping. The different strategies during stepping may result in different training effects and the biomechanical characteristics. The subjects had greater knee valgus moment during stepping pedal with trunk kept in a central position than the trunk medial-lateral shift [3]. Thus, the training effects of this stair climber on knee medial compartment osteoarthritis needs to be verified. However, in order to design proper exercise prescription for specific subject group, the investigation of biomechanical characteristics on different stepping strategies is needed.
Purpose: Thus, the purpose of this study was to investigate the differences of biomechanical characteristics between toe step and heel toe step together during stepping pinnacle trainer.
Methods: This study recruited 6 healthy participants who were excluded from musculoskeletal diseases. The mean age was 24.75 (1.50) years old, the mean height was 164.75 (11.70) cm, and the mean weight was 59.50 (15.33) kg. The stair climber (S770, SportsArt Fitness) was used. The loading level of this fitness equipment was set a level 1. The 3-D motion capture system (Raptor, Motion Analysis Corporation) was used to collect motion data during stepping the stair climber. A 6-axial force and torque sensor was used to collect foot contact force (Mini 85, ATI). Participants stepped this fitness equipment at their comfortable speed. There were two conditions, foot full contacts on the pedal (FC), and the other one condition was toe stepping (TS) at the terminal stepping phase. Every condition performed 5 trials and 15 seconds per trial. The cycle period contained the stepping phase which is a period when the pedal was at the highest position to the lowest of the track and the recovery phase which movement of pedal is inverse to the stepping phase.
Results: The ankle joint angle in sagittal plane showed a plantar flexion during TS condition at the terminal stepping phase. However, the FC condition showed a dorsiflexion at the terminal stance phase. The TS condition showed greater knee flexion angle than the FC condition. Both conditions showed a similar tendency in the hip joint angle in sagittal plane. In frontal plane, the TS condition had a greater inversion angle and a greater knee valgus angle. However, both conditions have a similar tendency in the hip joint angle in frontal plane. In joint moment comparison, the TS condition showed a greater plantar flexor and a greater hip extensor moment. Nevertheless, the knee extensor moment was smaller in the TS

condition compared to the FC condition. In the frontal plane, the TS condition showed a greater knee varus moment and a greater hip abductor moment, but a similar magnitude of ankle eversion moment.

Conclusion: This study investigated the differences of the biomechanics of the lower extremity between the TS and FC conditions. The current study identified the better stepping posture for exercise training for the different subject group. According to the results of knee joint moment in frontal plane, which showed a greater varus moment at terminal stepping phase in the TS condition than the FC condition. Thus, for the knee medial compartment osteoarthritis subject group, step with foot full contact on pedal may be recommended in order to decrease the medial compartment loading.

A TEMPORO-SPATIAL EVALUATION OF A STANDARDISED REHABILITATION REGIME DESIGNED FOR AN ADULT CEREBRAL PALSY PATIENT

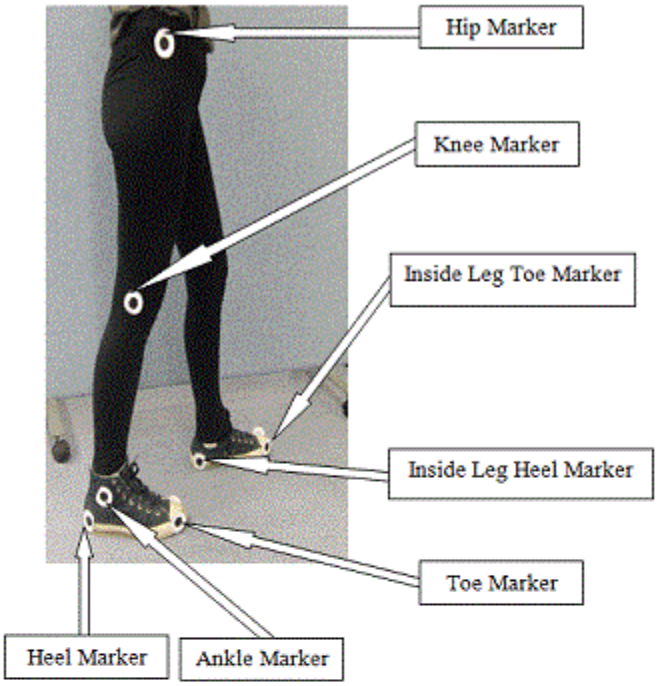
Ukadike C. Ugbolue [1,*] Fiona Henriquez [1] Philip Rowe [2]

[1]School of Science and Sport, University of The West of Scotland, Hamilton, [2]The Department of Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Cerebral Palsy (CP) is a perinatal disorder that is idiopathic in nature. As a consequence of growth this abnormality can progressively lead to secondary deficits such as bony deformities, muscle contractures, and gait abnormalities. [1] Although majority of the research in CP have been focused on children [1,2,3], there is a need to evaluate CP in adults so as to understand what changes occur with respect to their ambulation and joint mobility as they go about performing functional activities of daily living. Within our laboratory, a low cost two dimensional augmented video based portable system has been developed which can be used to evaluate CP gait as well as provide functional outcome measures that have strong clinical significance useful to clinicians and the allied health professionals. Indeed, there is still a dearth of knowledge with respect to how CP adults respond to functional activities of daily living. For that reason, it is necessary to design studies that can evaluate purposeful parameters leading to restoration of normal function and ability that describe functional deficits in response to routine activities of daily living. Therefore, the purpose of this pilot study was to evaluate a prescribed physiotherapy program designed for a cerebral palsy patient with mild walking difficulties.
Methods: This pilot study involved only one adult CP female patient aged 38 years old. The study monitored the patient throughout a rehabilitation process of prescribed exercise administered by a qualified physiotherapy practitioner. The study commenced from the onset of the rehabilitation process right through to the follow up session ten weeks after the baseline measurement. The study was laboratory based and performed at the biomechanics laboratory located at The University of The West of Scotland. The participant walked across a 6 metre long, high-contrast-grid vinyl mat while being video-filmed in the sagittal plane. Bi-directional temporo-spatial gait analysis and the production of sagittal plane estimates of joint kinematics were measured. This test was carried out on two occasions / time points (TP). TP1 was carried out prior to starting physiotherapy. TP2 was carried out ten weeks after starting physiotherapy. Seven strategically placed bulls-eye markers were placed on each heel, ankle, toe, knee and hip, covering ipsilateral and contralateral sides (Figure 1). Anthropometric measurements were obtained. The participant performed three gait cycles up and down the walkway grid mat barefoot at a self-generated walking speed. A three minute rest was observed. The participant performed three gait cycles up and down the walkway grid mat, this time wearing comfortable shoes (with splint) at a self-generated walking speed. The task orders were randomised. Video data was processed using the ProTrainer system (Sports Motion Inc®, Cardiff, CA) software. Descriptive statistics was applied. Step length variability was determined using the coefficient of variation (CV), where CV = (standard deviation / mean) x 100. The CV for the temporo-spatial measurement parameters were calculated using the mean of both legs averaged over all evaluated gait cycles.
Results: Both walking with splints and comfortable shoes and walking barefeet scenarios showed an increase in walking speed at TP2 for the left and right limbs (Figure 1). For the walking with splints and comfortable shoes task at TP2, the

percentage stance time reduced by 5% but increased by 0.5% during swing time. Conversely, the barefoot task showed a percentage stance time increment of 1.3% and a 1.3% swing time reduction at TP2. During the walking with splints and comfortable shoes task the CV for the left and right limb step length at TP1 (TP2) were 4.69% (2.13%) and 2.60% (4.53%) respectively. The CV for the left and right limb step length at TP1 (TP2) were 0.47% (4.97%) and 0.93% (10.39%) respectively for the barefoot task.

Figure:



(a)

Parameters for TP1 and TP2	Walking with Splint and Comfortable Shoes	Walking Barefoot
Walking Speed (m/s) for Right Limb (Mean (SD))	TP1: 0.952 (0.001) TP2: 0.977 (0.001)	TP1: 0.821 (0.001) TP2: 0.881 (0.001)
Walking Speed (m/s) for Left Limb (Mean (SD))	TP1: 0.921 (0.003) TP2: 0.968 (0.001)	TP1: 0.843 (0.003) TP2: 0.868 (0.001)
Percentage (%) Stance Time	TP1: 67.18 TP2: 66.18	TP1: 65.38 TP2: 66.68
Percentage (%) Swing Time	TP1: 32.82 TP2: 33.32	TP1: 34.62 TP2: 33.32
Right Limb Step Length (cm)	TP1: 58.15 (1.50) TP2: 60.48 (2.74)	TP1: 53.49 (0.50) TP2: 55.43 (5.76)
Left Limb Step Length (cm)	TP1: 58.37 (2.74) TP2: 57.71 (1.25)	TP1: 52.60 (0.25) TP2: 50.30 (2.50)

(b)

Caption: Figure 1: (a) Volunteer marked with black-and-white bull's eye markers (b) Measurement outcome parameters for Adult CP pilot study at different time points (TP).

Conclusion: The spatial parameters showed low levels of CV. The percentage stance and swing time temporal parameters showed variable results at TP1 and TP2 when both tasks were performed. In terms of consistency between tasks and TPs, walking speed appears to be a variable outcome measure useful for evaluating the efficacy of the administered standard rehabilitation regime.

PO-0270

THE EFFECT OF SCHOOL TROLLEY LOAD ON SPATIOTEMPORAL GAIT PARAMETERS OF CHILDREN

Eva Orantes-González [1,*] Jose Maria Heredia-Jiménez [1] Victor Manuel Soto-Hermoso [1]

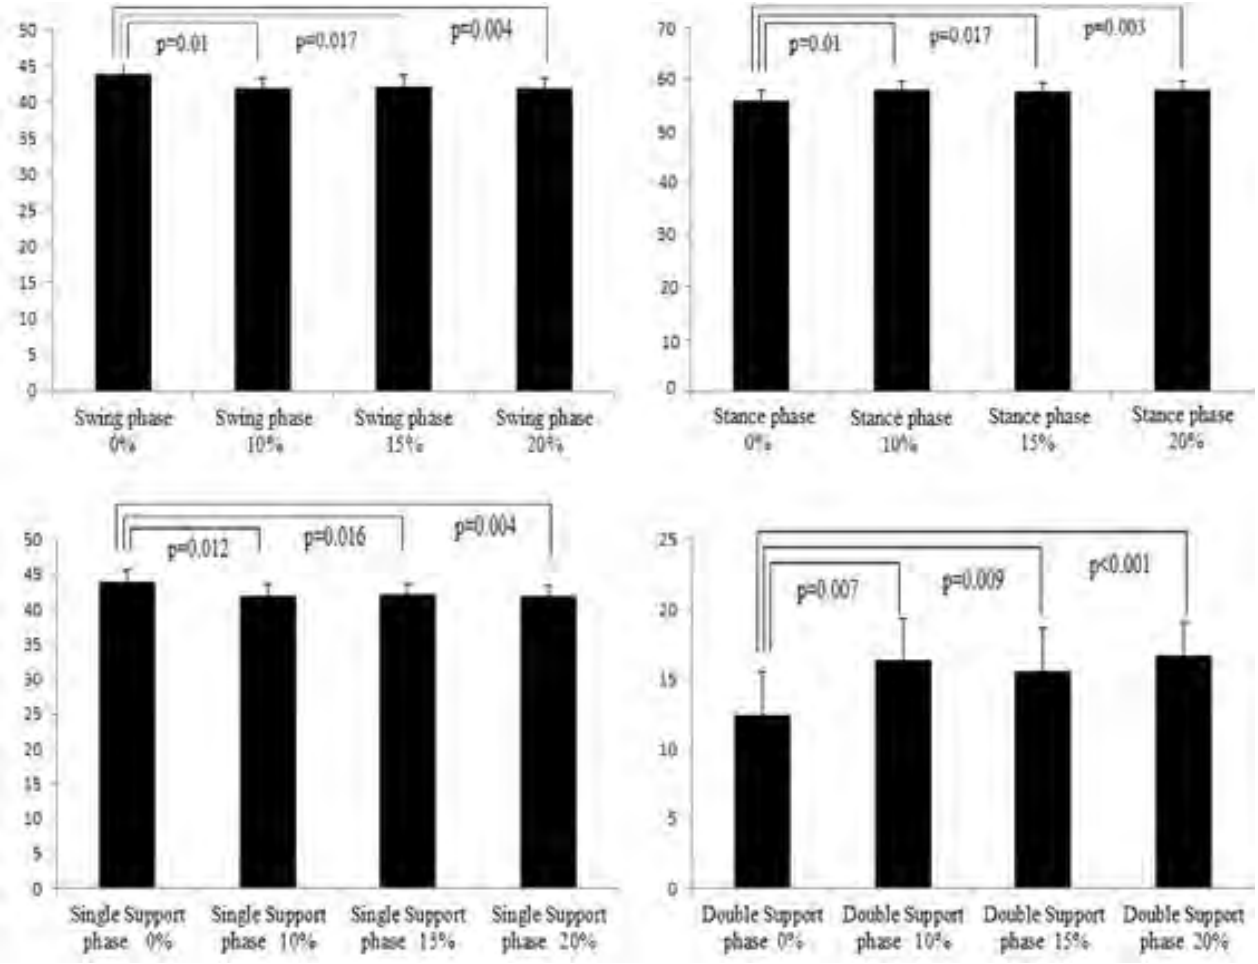
[1]Physical Education and Sport, University of Granada, Granada, Spain

Introduction and Objectives: Every day children have to carry a backpack full of books to school, which has traditionally been the most common modality of transport(1). Transporting a backpack over one or two shoulders has been widely studied. Changes in gait, energy expenditure and balance have been analysed with backpacks of different loads(2-6). Recently, a new form of carrying backpacks has appeared on the market: wheeled backpacks or school trolleys(7). Our research in the literature has not found any investigation in respect to gait when using school trolleys. The increase in the use of school trolleys has made a deeper and wider knowledge about this mode of school transport children. It becomes more important as children experience significant growth and motor development(6). Therefore, the purpose of this study was to determine the effect of using a school trolley with different loads on spatio-temporal gait parameters of children on students of a primary school.

Methods: Fourteen students of a primary school(aged 11.43±0.51 years) participated in this study. The average body weight was 35.06±10.07kg and average body height was 1.42±0.09m. To analyse the effect of increased loading on school trolleys, we used four conditions: without trolley (represented 0% body weight)(0%BW), 10%, 15% and 20%BW. The different loads were achieved filling the trolley with books of different weights. Each child was weighed and measured(SECA769,Hamburg,Germany). After, subjects completed 5 trials walking comfortably along a pressure mat(GAITRite system;CIR Systems Inc.,NJ,USA) without trolley and 5 trials walking with the 3 load conditions (10%,15% and 20%BW) in a randomized order. The mat was positioned on the centre of the walkway and cones were placed at 3 metres from the start and the end of the mat to be sure that arrived with a stable gait. Spatiotemporal parameters were analysed: velocity(cm/s); cadence(steps/min); stride length(cm), swing (%Gait Cycle)(%GC), stance (%GC), single support (%GC) and double support phase(%GC). Analysis of data was done with SPSS(SPSSv.20, SPSS Inc., Chicago IL). The Shapiro Wilk´s test was used to test normal sample and repeated measures ANOVA to compare the different load conditions.Bonferroni test was applied for pair comparison. Level of significance was set at $p < 0.05$.

Results: Results showed a non-significant difference in velocity and stride length when children walked without a school trolley compared with pulling it with the different loads($p=0.116$;$p=0.773$ respectively). With respect to cadence, showed significant increase comparing 10, 15 and 20%BW load conditions with control level(0%BW)($p<0.001$;$p=0.002$;$p<0.001$respectively).Comparing with control level, swing and single support phase decreased significantly when load increased and stance and double support phase significantly increased when load increases(fig.1). None of the gait parameters studied showed significant differences between load conditions(10% and 15%>20% nor between 15% and 20%BW).

Figure:



Caption: Figure 1. Swing phase (%); stance phase (%), single support (%) and double Support (%).

Conclusion: Gait parameters related to pulling school trolleys with different loads have not been investigated before to our knowledge. Pulling a school trolley with 0%,10%,15% and 20%BW did not affect velocity and stride length.Previous studies have analysed the transport of asymmetrical loads obtaining lower velocity when children walked with 17%BW in a backpack carried in their hands(8).Cadence significantly increased when children carried 10, 15 and 20%BW when compared with no load conditions. That motivated a non-significant increase in velocity because the children used to adjusted their cadence to effect the change in speed. Stance and double support phase were higher when children walked in the three load conditions compared with no load. Kellis and Arampatzi(8) explained this increasing because when children walked with a loaded school trolley increase the instability and they have to increase the stance and double support phase to maintain their balance (9). Consequently it produced a decrease in the swing and single support phase when load was higher compared with no load conditions. We would highlight that in none of the spatio-temporal gait parameters analysed in this study showed significant changes between 10% and 15%BW,10 and 20%BW and nor between 15 and 20%BW conditions. So carrying a school trolley with a load produces significant changes with respect to normal gait, but increasing load(range to 10-20%BW)did not produce significant differences in gait parameters.

PO-0271

RELIABILITY OF A MARKER-BASED LOCATOR FOR MEASURING IN VIVO THREE-DIMENSIONAL SCAPULAR POSES USING STEREOPHOTOGRAMMETRY

Mei-Ying Kuo [1 2,*] Tung-Wu Lu [2 3] Jia-Da Li [2]

[1]Department of Physical Therapy, China Medical University, Taichung, [2]Institute of Biomedical Engineering, [3]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Accurate measurement of the three-dimensional (3D) scapular kinematics is essential for a better understanding of the mechanical interactions between the scapular and the other segments of the shoulder complex. However, precise measurement of the scapular kinematics is difficult because the scapular moves greatly underneath the skin during dynamic activity. Previous studies have used magnetic tracking devices with a scapular locator to measure the poses of the scapula [1]. Since skin marker-based stereophotogrammetry has been widely used for motion analysis in basic research and clinical applications, there is a need to develop such locators for measuring scapular poses. Therefore, the purposes of the study were (1) to development a marker-based scapular locator for measuring scapular poses and (2) to determine the intra-rater and inter-rater reliability of the locator.

Methods: An adjustable marker-based scapular locator was developed and used to measure the scapular poses by pointing to the root of spine (RS), the inferior angle (IA) and the acromial angle (AA) of the scapular with its three legs (Fig. 1). Twenty-two healthy volunteers without shoulder pathologies participated in the current study with informed written consents as approved by the IRB. Each subject was tested separately by two raters (A and B) using the marker-based scapular locator while performing static shoulder flexion at 20, 40, 60, 80, 100 and 120 degrees in the sagittal plane. The marker positions were measured using a seven-camera motion analysis system (Vicon 370, Oxford Metrics, U.K.) at 60Hz. The reliability models, $ICC_{(2, k)}$ and $ICC_{(3, k)}$, were used to analyze the intra-rater and inter-rater reliability for scapular of positions of the AA, RS and IA and the three scapular rotations. An ICC value of 0.8 to 1.0 indicates a very good reliability, 0.61-0.8 good, 0.41-0.6 moderate, and below 0.2 is a poor reliability. All statistical analysis was performed using SPSS 13.0 (SPSS Inc., Chicago, USA).

Results: For the intra-rater reliability, the ICC ranged from 0.81-0.97 and 0.89- 0.99 for rater A and rater B for the scapular rotations in each arm elevation position. The ICC ranged from 0.88 to 0.99 by the two raters for the positions of the AA, IA and RS for shoulder flexions at 20, 40, 60, 80, 100 and 120 degrees in the sagittal plane. For the inter-rater reliability, the values of the ICC ranging from 0.92 to 0.99 were found for scapular rotations and positions for shoulder flexion at 20, 40, 60, 80, 100 and 120 degrees in the sagittal plane.

Figure:

Caption: The three legs of the marker-based scapular locator can be moved to point to the AA, RS and IA of the scapula, and then fixed by the bolts.

Conclusion: The results showed that very high intra- and inter-rater reliability for scapular rotations and for the AA, RS and IA positions were achieved using the locator. Two main reasons led to this effect: (1) design of the scapular indicator and (2) careful palpation of the bony landmarks over the scapula. The new design of the marker-based scapular locator overcame the limitation of three-point scapular locations [1], which was unable to adjust three pointers to adapt different size of the scapula. The current results show that the new locator is helpful and reliable in the measurement of the scapular poses for research and clinical applications.

PO-0272

THE EFFECTS OF LOAD CARRIAGE AND SPEED ON THE BIOMECHANICAL RESPONSES OF THE SOLDIER DURING UPHILL, DOWNHILL AND LEVEL WALKING

Caley Chaplin [1,*] Heinrich Nolte [1]

[1]Research and Development, Ergonomics Technologies, Pretoria, South Africa

Introduction and Objectives: Load carriage systems (LCS) are used to transport equipment and supplies over extensive distances and unpredictable terrain, especially in a military application. The advancement in technology has resulted in soldiers carrying loads that very often exceed 50% of body weight. LCS impact soldier performance and combat readiness and therefore an understanding of the physiological and biomechanical impact on the soldier is crucial in preventing injuries and enhancing performance. The majority of load carriage research has focused on the physiological effects but more recently there has been a shift in focus to the biomechanical impact. There is a lack of evidence however explaining the linear kinetics of walking downhill with a load and how this compares to walking level and uphill. Increases in ground reaction forces (GRF) and changes to the typical gait pattern as a result of additional loads and change in gradient have been linked to the cause of overuse injuries such as shin splints, blisters and stress fractures (Birrell et al., 2010). The objective of this study is to therefore determine the effects of load, speed and gradient on the biomechanical responses of the soldier. These findings will contribute to understanding the mechanisms of gait and reducing biomechanical stress placed on the body to prevent injuries specifically during downhill walking.

Methods: Sixteen soldiers (14 males and 2 females) walked on an instrumented treadmill at two speeds of 4km/h and 5km/h with and without a load on their back at decline (-10%), flat (0%) and incline (+10%) gradients. The load consisted of a military type backpack external frame with shoulder straps and a hip belt and 35kgs of barbell weights placed between the shoulder blades at the level of the 4th thoracic vertebra. The Qualisys Motion Capture System was used in conjunction with the Bertec™ Instrumented Treadmill to obtain the kinetic and kinematic responses of the soldiers. However, this paper will only discuss the linear kinetics during downhill walking. All force data was normalized according to body mass and additional load carried and analyzed using STATISTICA Version 12.

Results: Decline walking resulted in significant increases in peak loading rates, impact peak loads, braking forces and significant decreases in propulsive forces when compared to level and incline walking. Decline walking resulted in the first peak GRF to be 11% higher than incline walking and the second peak GRF to be 16% lower than incline walking. Walking at 5km/h compared to 4km/h resulted in significant increases in peak loading rates and impact peaks. The peak loading rates, vertical impact peak and anterio-posterior braking forces were significantly lower during the loaded condition compared to the unloaded condition during downhill walking. In addition, the first half of the stance phase was found to be significantly longer when carrying a load during level and decline walking which explains the reduction in forces during load carriage.

Caption: Figure 1: The mean peak loading rate (N/s/kg) during level, uphill and downhill walking with and without a load

Conclusion: Previous research (McNally, 2010) has identified uphill walking as significantly more physiologically taxing than downhill walking and therefore a key factor in regulating walking speed during a military route march. However the

significantly larger GRFs measured during downhill walking suggest that a reduction in speed can be used as an effective strategy in reducing these high forces and risk of injury. The findings from this study highlight the importance of pacing strategies as an effective technique to mitigate forces especially during loaded downhill walking. An increased stance time was found during load carriage when walking downhill suggesting that individuals adopt protective mechanisms to mitigate additional force. Additional strategies such as increased muscle activation; greater joint flexion (Polcyn et al., 2002) and postural adaptations may also be used to increase absorption of force when carrying additional loads. LCS design should focus on reducing the impact peak and maximum braking force as this has been strongly associated with the development of acute and overuse injuries (Birrell et al., 2010). These findings can be used to provide recommendations on safe load carriage practices to the military in order to enhance soldier performance and reduce the risk of injuries to the lower body.

DEVELOPMENTAL PROCESS OF "FORESEE-MOVEMENT" IN YOUNG CHILDREN CATCHING A BOUNCING BALL

Mami Umemoto [1,*] Chiaki Ohtaka [2] Motoko Fujiwara [3]

[1]Human Behavioarl Sciences, Guraduate School of Humanities and Sciences, [2]Human Sciences, Guraduate School of Humanities and Sciences, Nara Women's University, [3]Faculty of Human Life and Environment, Nara Women's University, Nara, Japan

Introduction and Objectives: The period of childhood is important for the development of fundamental movement. Exercise during this period promotes nervous system development for exercise performance and can affect movement abilities in adolescence. Young children acquire a variety of movement through play and activity in their daily lives. Children also acquire the abilities to anticipate the movement of a target or to estimate their own movement. We define "foresee-movement ability" as the abilities to anticipate and estimate. The purpose of this study was to examine the developmental process of "foresee-movement" in young children catching a bouncing-ball.

Methods: The participants were 139 children between 3 and 5 years old (3-year-old children: 23, 4-year-old children: 56, 5-year-old children: 60). The tasks were to catch a bouncing ball in following two manners. One was a straight-line task. In this task, an experimenter dropped the ball from a height of about 1.6m from the floor at a point 1m in front of the participant. The participant was told to move to the drop point and catch the ball after the first bounce. The other task was parabolic-line task. In this task, an experimenter threw the ball to a height of about 1.6m from the floor toward a drop point 2m in front of the participant. The participant was told to move forward 1m and catch the ball after the first bounce.

The participants' catching movement was recorded from the right side by video cameras.

We analyzed four items in the data. First, we divided catching movement by success or failure. If the participants were able to catch the ball before the second bounce, it was considered a success; the other trials were classified as failures. Second, we analyzed "Total motion time" between the beginning of the motion to catching the ball. "Total motion time" was divided into two phases, "Estimate time" "Movement time" with a border, the beginning of the participant's motion. Third, we checked the distance of the catching point. Finally, we classified "Catching Movement-pattern" into some categories based on active or still, success or failure to catch the ball, and manner of catching.

Results: The catching rates increased with age in both tasks. The straight-line task had a higher success rate than the parabolic-line task (Figure 1).

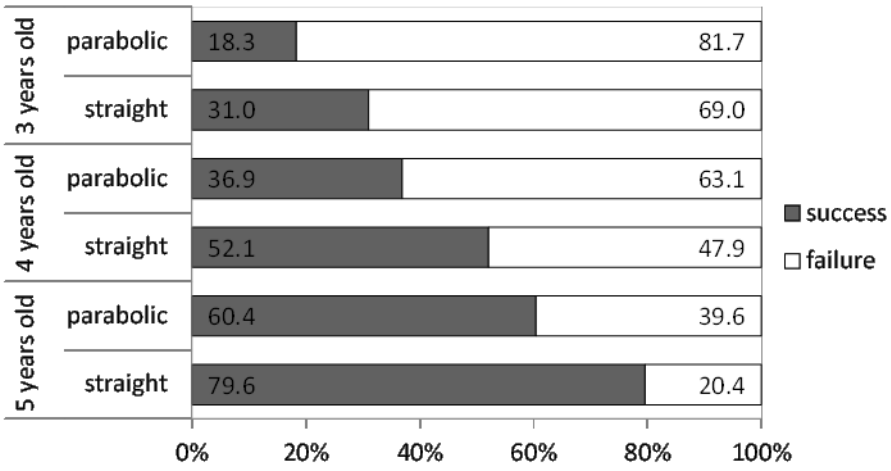
The catching movement-pattern was classified into six patterns: (1) no movement, (2) the ball bounced once and passed over the head, (3) the ball was caught after two bounces, (4) an attempt was made to catch the ball after one bounce, but the ball could not be touched, (5) an attempt was made to catch the ball after one bounce, but the ball was knocked away, and (6) the ball was caught after one bounce.

In the straight-line task, the total motion time and the movement time shortened in accordance the participant's age of the moon. Patterns 3–5 accounted for many aspects of the movement-pattern of 3-year-old and 4-year-old children.

In the parabolic-line task, the total motion time and the movement time shortened with participant's age of the moon, and the estimate time lengthened. The movement-pattern of the 3-year-old and 4-year-old children was classified into patterns 1–3. Many of the movement-patterns in the 5-year-old children, on the other hand, were classified as pattern 5.

In both the straight-line and parabolic-line tasks, the catching movement was done around the highest point after the first bounce. Movement-pattern 6 was significantly increased from 4-year-old through 5-year-old children.

Figure:



Caption: Figure 1. The catch success rate with the age in parabolic- and straight-line tasks.

Conclusion: The specific characteristics of young children's movements include catching at the high point above the neck. It is obvious that young children are able to anticipate the track of the ball and estimate their own movement increasingly with age. Foresee-movement is gradually developed along with age even if catching movement is classified as failure-pattern.

Multi-dimensional spatial expectation—for example, the parabolic-line task—is difficult for 3-year-old. We suggest that 3-year-old children start simple tasks or interact with the ball and that ball play should be adopted with orbital prediction after 4-years-old.

PO-0274

KINETIC ANALYSIS OF ROTATIONAL MOVEMENT OF LOWER TRUNK IN BASEBALL TEE-BATTING

Kazumichi Ae [1,*] Sekiya Koike [2]

[1]School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom, [2]Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan

Introduction and Objectives: A baseball batter is required to increase bat-head speed as much as possible to hit a long ball. The bat-head speed is generated by utilizing a kinetic link transferring energy up from the lower extremities through successive body segments (Welch et al., 1995). In order to make clear the effective movements of the lower extremities, kinetic analyses of the lower extremities have been reported by evaluating the pattern of ground reaction forces. Although, Takagi et al. (2010) analyzed the kinetic features of the lower extremities on torso motion under different ball speeds condition in order to clarify the mechanisms of the trunk rotation; the study focused on the mechanical power at the individual hip joints. It is, therefore, still unclear how the individual hip joints contribute the rotational movement of the lower trunk. The purpose of this study was to investigate the kinetic mechanisms of the trunk rotation in baseball tee-batting.

Methods: Ten male collegiate baseball players (age: 20.7±1.1 yrs., height: 1.75±0.05 m, weight: 76.3±7.1 kg, athletic career: 12.7±2.7 yrs.) participated in this study. They performed baseball tee-batting with a middle ball height (belt height) condition. Three-dimensional coordinate data were captured with a motion capture system (VICON MX+, 16-cameras, 250 Hz). Ground reaction forces of individual feet were measured with force platforms (1000 Hz). The joint kinetic data of the individual lower extremities were calculated using inverse dynamics. The equation of rotational motion of the lower trunk segment can be expressed as follows:

$$I_{LT}\alpha_{LT}+\omega_{LT}\times(I_{LT}\omega_{LT})=N_{PS,Hip}+N_{SS,Hip}-N_{Trk}+N_a+N_b+N_c$$

$$N_a=r_{LTcg\text{-}PS,Hip}\times F_{PS,Hip},\ N_b=r_{LTcg\text{-}SS,Hip}\times F_{SS,Hip},\ N_c=-r_{LTcg\text{-}Trk}\times F_{Trk}$$

(LT: lower trunk, PS: pivot side, SS: step side, Trk: trunk, cg: center of gravity)

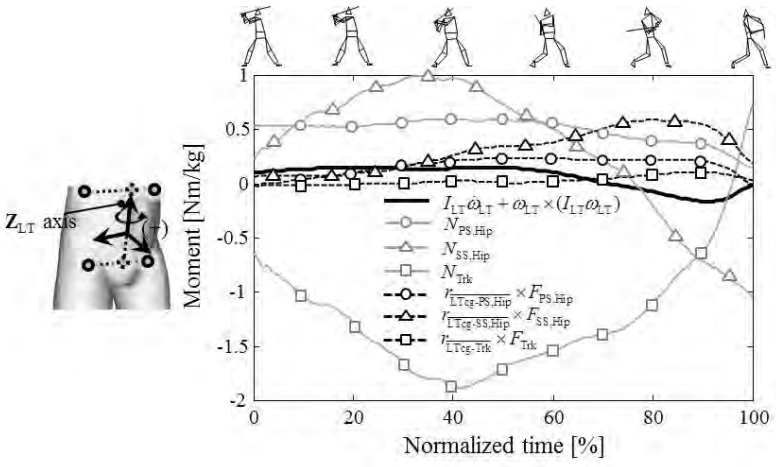
where I_{LT} is the moment of inertia of the lower trunk segment, α_{LT} is the angular acceleration of the lower trunk segment, ω_{LT} is the angular velocity of the lower trunk segment, $r_{LTcg\text{-}i}$ is the vector from the cg of the lower trunk segment to individual joint center, $I_{LT}\alpha_{LT}+\omega_{LT}\times(I_{LT}\omega_{LT})$ is the inertial moment, $N_{PS,Hip}$, $N_{SS,Hip}$, N_{Trk} are individual joint torques, and N_a, N_b, N_c are individual moment caused by the joint forces. In addition, the coupled force ($r_{LTcg\text{-}i}\times F_{cf,i}$, CF: coupled force) of the joint force at the individual hip joints was estimated.

These kinetic data of all subjects were normalized by the time of the step-side foot contact to the ball impact as 0 to 100%. The period was divided into two phases (1st phase: 0-50%, 2nd phase: 50-100%) for the analysis and description of data.

Results: Figure 1 shows the averaged patterns of Z axial moment about the lower trunk segment. The trunk joint torque (N_{Trk}) had a significant negative value among the other joint torques, and the peak value was observed at 40% time. The pivot-side hip joint torque ($N_{PS,Hip}$) was almost constant value. The step-side hip joint torque ($N_{SS,Hip}$) increased until around 30% time and decreased gradually around 70% time, and then changed to a negative value. The moment caused

by the step-side hip joint force ($r_{LTcg\text{-}SS,Hip} \times F_{SS,Hip}$) increased from 40% to 80% time and became the greatest value among the moments caused by other joint forces. Table 1 indicates the averaged values of Z axial components of moment exerted on the lower trunk segment in the phases. In the first phase, the joint torques were greater than the moments caused by joint forces, and trunk joint torque (N_{Trk}) showed a significant negative value. The coupled force at the individual hip joint force terms was small and was similar to the value of the trunk joint force term. In the second phase, the trunk joint torque also had a significant negative value, and the step-side hip joint torque decreased significantly. The moments caused by the hip joint forces and the coupled force included in the hip joint force were greater than those values in the first phase.

Figure:



Caption: Figure1 Averaged patterns of the Z axial moment about the lower trunk segment ((+): batted ball's direction, (-): catcher's direction).

Conclusion: We focused on the relationship between the individual hip joints and the rotational movement of the lower trunk segment because the hip joint torques were greater than the other joint torques. It was clear that the torques of both hip joints contributed largely to the generation of Z axial moment of the lower trunk segment.

Table:

	1st Phase	2nd Phase
$I_{LT}\alpha_{LT}+\omega_{LT}\times(I_{LT}\omega_{LT})$	0.124	0.002
$N_{PS,Hip}$	0.535	0.442
$N_{SS,Hip}$	0.723	0.077
N_{Trk}	-1.303	-1.177
$r_{LTcg\text{-}PS,Hip}\times F_{PS,Hip}$	0.090	0.195
$r_{LTcg\text{-}SS,Hip}\times F_{SS,Hip}$	0.097	0.423
$r_{Trk}\times F_{Trk}$	-0.017	0.041
$r_{LTcg\text{-}PS,Hip}\times F_{CF,PS,Hip}$	0.019	0.166
$r_{LTcg\text{-}SS,Hip}\times F_{CF,SS,Hip}$	0.019	0.166

PO-0275

DEFINING MIDSTANCE IN DIFFERENT POPULATIONS

Catriona M. Kerr [1,*] Julie Stebbins [2] Amy Zavatsky [1]

[1]Engineering Science, University of Oxford, [2]Oxford Gait Laboratory, Nuffield Orthopaedic Centre, Oxford, United Kingdom

Introduction and Objectives: Event-driven analysis of the gait cycle avoids the effects of time averaging. Midstance is one such event; however, this event has many definitions:

- Halfway between foot contact and foot off. This may not represent a comparable point in different subjects, particularly those with pathology. Also, patients who drag their feet do not show clean foot strike and foot off events.
- The instant where the long axis of the tibia is vertical.
- The time at which the foot is most flat, though this may represent an extreme posture.
- The Vertical Ground Reaction Force (VGRF) allows the finding of a local minimum (which closely corresponds to the maximal vertical body height).

The aim of this study was to compare these definitions as applied to data from different populations seen in a clinical gait laboratory and to identify an event-driven, kinematically-repeatable time-point during the foot flat period of midstance.

Methods: Six populations (n=203) were included in this study (Table). Retro-reflective markers were applied to the feet and limbs at known anatomical landmarks [1]. 12-16 infra-red cameras (Vicon-MX, Oxford, UK) were used to track the marker positions (100 Hz), alongside 3 AMTI force-plates (Advanced Mechanical Technology, Inc., Watertown, MA, USA) collecting VGRF data (1000 Hz). Data was recorded for at least three separate walking trials with clean force-plate strikes per limb. Trials were processed using Vicon Nexus software. Small gaps were handled by interpolation using cubic splines [2] or by assuming constant distance between markers on the same segment [3]. A Woltring filtering algorithm was used [4]. Foot strike and foot off events were determined using VGRF where possible (else manually). Thigh wand offsets were iteratively determined (minimising ab-/ad-duction occurring at the knee) [5].

Halfway between foot strike and foot off was defined as 50% stance. The vertical tibia event was when the tibial segment first became vertical in the sagittal plane. The time at which the vertical sum of all foot mounted markers was closest to zero was defined as the flattest foot event. The first and second VGRF peaks closest to 25% and 80% stance were identified from VGRF data smoothed with a moving average filter with a span of 5 frames. The minimum VGRF between these events was the fourth definition. For each definition, 14 lower-limb kinematic angles and the intra-subject and inter-subject variability were calculated:

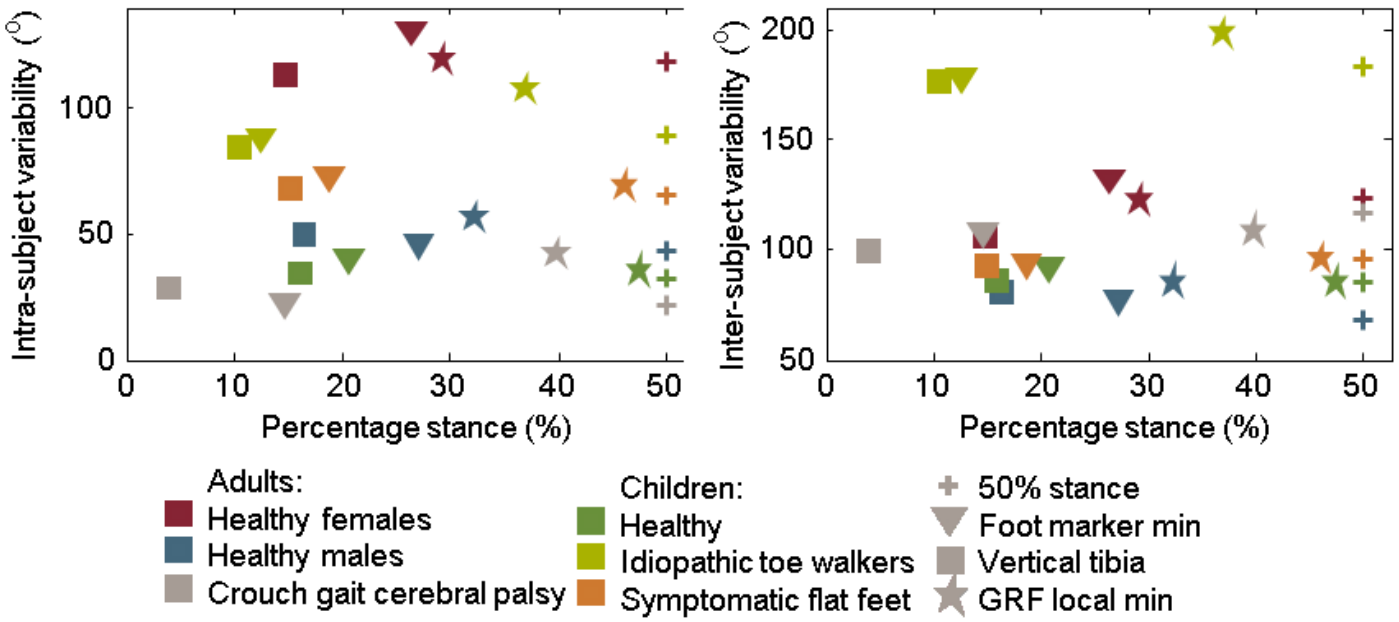
$\text{Intra-subject variability}_{\text{event, population}} = \Sigma_{\text{angle}} (\text{mean}_{\text{subject}} (\text{s.d.}_{\text{trials}}(x)))$;

$\text{Inter-subject variability}_{\text{event, population}} = \Sigma_{\text{angle}} \text{s.d.}_{\text{subject}} (\text{median}_{\text{trials}}(x))$;

Where x refers to the kinematic angle found for a subject, event, and trial. The sub-scripts indicate to which set of data the operation should be applied.

Results: All events in all populations occurred on average prior to 50% stance (Figure), especially vertical tibia and flattest foot. Adult females demonstrated most intra-subject variability, adults with crouch gait the least. Idiopathic toe walkers were the most variable inter-subject.

Figure:



Caption: Intra- and inter-subject variability per group.

Conclusion: This study investigated the timing and variability of lower-limb posture using 4 midstance definitions and 6 subject groups.

The timing of vertical tibia was the earliest, particularly amongst those with crouch gait (probably due to knee flexion). The foot marker sum also occurred early in stance; this may be related to the larger VGRF in early stance. The VGRF minimum timing was closer to 50% stance.

Intra- and inter-subject variability was more different between groups than between midstance definitions. Adult females had the most intra-subject variability; mostly in ankle and foot angles. Those with crouch gait had least variability across all midstance definitions. This may reflect differences in angular range of motion. Inter-subject variation was greatest for toe walkers; this was due to ankle and hallux flexion variation. The increased variability may reflect differing degrees of equinus severity.

This investigation into the variability and timing of four midstance definitions revealed the study group to be an important factor. Vertical tibia and flattest foot midstance definitions describe a point early in stance, sometimes within the double support phase, making them less suitable midstance events. VGRF minimum and 50% stance are closer in time, and similar in variability.

Table:

Adults		Children	
Healthy_Female	n= 22	Normal	n= 88

EFFECTS OF OBSTACLE HEIGHT ON THE JOINT MOMENTS OF THE LOWER EXTREMITIES WHEN CROSSING OBSTACLES WITH HIGH-HEELED SHOES

Kao-Shang Shih [1 2,*] Hui-Lien Chien [3] Tung-Wu Lu [3 4]

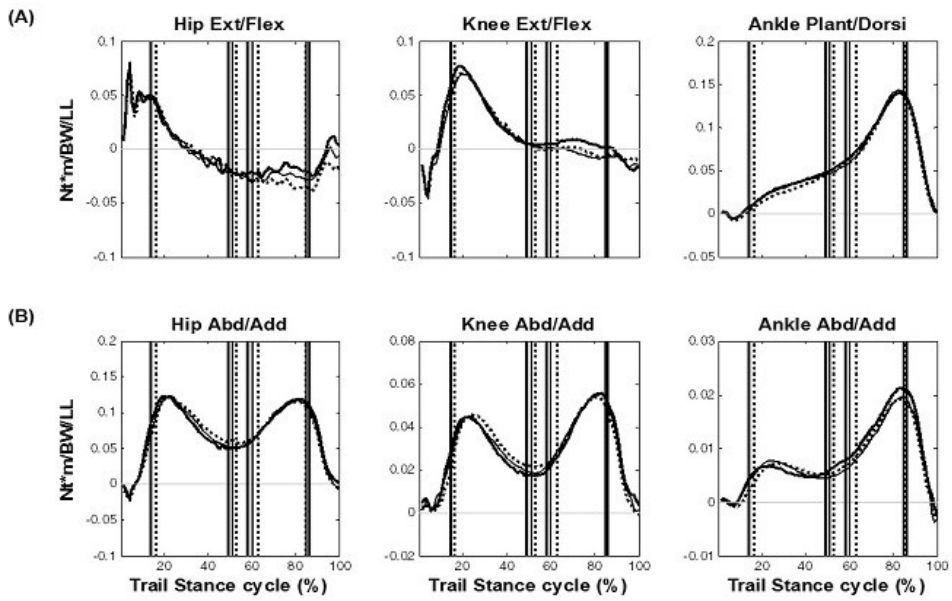
[1]Shin Kong Wu Ho-Su Memorial Hospital, Department of Orthopedic Surgery, Taipei City, [2]School of Medicine, Fu-Jen Catholic University, New Taipei City, [3]Institute of Biomedical Engineering, National Taiwan University, [4]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei City, Taiwan, Republic of China

Introduction and Objectives: In modern society, many women wear high-heeled shoes in both professional and social settings. High-heeled shoes with a reduced support base increase the difficulty of maintaining balance, and thus the risk of falling, leading to injuries such as fracture and ankle sprains. This challenge is increased by the presence of obstacles. Apart from the precise end-point control for sufficient foot-obstacle clearance of the swing limb, a successful and safe obstacle-crossing also requires the stability of the body provided mainly by the stance limb. Loss of balance is one of the major causes of falls during ambulation while negotiating obstacles. The purpose of the present study was to investigate the influence of obstacle height on the joint moments of the lower extremities when crossing obstacles with high-heeled shoes.

Methods: Twelve female wearers (age: 24.3±3.8 years; height: 157.3±4.8 cm; mass: 48.8±4.6 kg) participated in the current study with informed written consent, as approved by the Institutional Research Board. They crossed obstacles with heights of 10%, 20% and 30% of their leg lengths when wearing high-heeled shoes. The high-heeled shoes were narrow-heeled (heel base: 2.0 cm x 1.6 cm; heel heights: 6.3 cm) and were commercially available. Each subject wore 39 retroreflective markers for tracking motions of the body segments. The kinematic data were measured using a 7-camera motion capture system (Vicon 512, OMG, UK) and the ground reaction forces were measured using two forceplates (AMTI, USA) placed on each side of the obstacle. Six successful trials, three for each limb, were obtained. With the measured GRF and kinematic data, inverse dynamics were used to calculate the intersegmental moments at the lower limb joints. Inertial properties for each body segment were obtained using Dempster's coefficients. The joint moments of the trailing limb when the leading toe was above the obstacle were extracted and analyzed using one-way repeated measures ANOVA. Whenever a height effect was found, a polynomial test was performed to determine the linear trend. All significance levels were set at $\alpha=0.05$. SPSS version 17.0 (SPSS Inc., Chicago, USA) was used for all statistical analyses.

Results: When the leading toe was above the obstacle, subjects showed linearly increased knee extensor moments but linearly reduced ankle plantarflexor moments with increasing obstacle height (Table 1). Abductor moments at the hip and knee were also reduced linearly.

Figure:



Caption: Ensemble-averaged joint moments of the hip, knee and ankle joints of the trailing limb in the (A) sagittal and (B) frontal planes when crossing obstacle of 10% (dashed lines), 20% (solid lines, thin) and 30% (solid lines, thick) conditions with high-heeled condition. Vertical lines indicate the time when the leading swing toe above the obstacle. Ext/Flex: extensor/flexor; Abd/Add: abductor/adductor; Plant/Dorsi: plantarflexor/dorsiflexor; Pro/Sup: pronator/supinator)

Conclusion: With increasing obstacle height, the mechanical demands to the ankle plantarflexors, and hip and knee abductors were all reduced linearly, primarily because the stance limb became more extended. In contrast, the knee extensor moments of the trailing stance limb was increased. This strategy relies on the knee extensors to provide the whole body support when facing obstacles with increasing height. Therefore, inability to recruit the knee extensor muscles or weakness of the knee extensors, such as resulting from aging, may lead to an increased risk of unsuccessful obstacle-crossing. Further study on the older population is needed. The current results may be helpful for the development of strategies aiming at minimizing the risk of falls during obstacle-crossing in high-heeled shoes.

Table:

	Obstacle height (% leg length)			Effects
	10%	20%	30%	
Knee extensors	0.2 (1.2)	0.4 (1.4)	0.7 (1.2)	increase
Ankle Plantarflexors	5.0 (1.3)	4.8 (1.5)	4.8 (1.6)	decrease
Hip abductors	5.9 (1.2)	5.2 (1.1)	5.0 (1.2)	decrease
Knee abductors	2.2 (0.9)	1.9 (0.9)	1.8 (1.0)	decrease

Caption: Means (standard deviations) of the joint moments in the sagittal and frontal planes for the trailing stance limb when the leading toe was above the obstacle with high-heeled condition. ‘Increase’ indicate linearly increasing trend while ‘decrease’ arrows indicate linearly decreasing trend ($p<0.05$). Units: %BW*LL.

PO-0277

CHARACTERIZATION OF SURF POP-UP SIMULATED MOVEMENT

Marcio Borgonovo-Santos [1] Sara Morais [2] Marcelo Castro [3] Pedro Fonseca [2] Pooya Soltani [1] Andréia Flores [2] João Paulo Vilas-Boas [1,*]

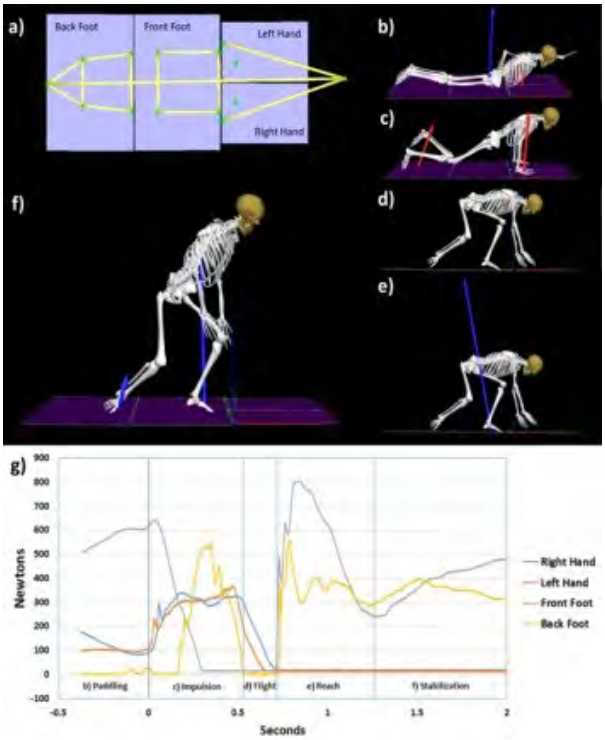
[1] Biomechanics Laboratory of Porto - LABIOMEP, Faculty of Sports - University of Porto (FADE-UP), [2] Biomechanics Laboratory of Porto - LABIOMEP, Porto, Portugal, [3] School of Physical Education, Sport and Exercise Science, University of Otago, Dunedin, New Zealand

Introduction and Objectives: The pop-up is one explosive movement executed to stand up quickly on the surfboard. This movement defines the transition from the horizontal to vertical phase of surfing. After paddling the hands are supported in parallel on the surfboard, under the chest. An extension of the arms is held to promote a strong impulse to take-off, the feet are guided to the back deck and front deck of the surfboard, after that stabilize the body. The pop-up movement separates the successful surf riding or not. Because this is important to understand how this technic works. The main objective of this study is to characterize the pop-up simulated movement on dry land (laboratory conditions). Kinematic analysis was used to explore the best way to divide the movement, and kinetic analysis was used to explore differences between dominant and non-dominant upper and lower limbs.

Methods: The Ethics Committee of the Faculty of Sport from the University of Porto approved this project with the process CEFADE 27-2014. Seven recreational surfers, who practice the activity regularly (age = 31±6yrs, height = 1.77±0.03m, mass = 72±9kg, surf experience = 17±3yrs, frequency of training = 3 times/week) were evaluated performing a pop-up maneuver over force platforms on dry land. This was done on a drawn surfboard layout (6 foot and 2 inches size) over four Bertec force plates (Fig. 1.a.), synchronized with 12 Oqus cameras from the 3D motion capture system (Qualisys AB, Gothenburg, Sweden). Movements were tracked with 48 retro-reflective markers (full body setup) and recorded at 200 Hz. Data analysis was performed with Visual 3D Professional (Visual3D, C-Motion, Kingston, Canada). Forces were normalized according to the subject's body weight. The following outcomes were calculated: upper limbs impulsion peak force percent, lower limbs land peak force percent. Paired T-tests were applied to verify differences between forces applied by the dominant and non-dominant upper limbs, as well as between the lower limbs (front and back on the surfboard).

Results: The movement began when the surfer´s hand touched the force plates, the results indicated that the subjects took 1.40±0.52s to perform the movement (touch the hands on the force plates, stand-up and stabilize). The dominant upper limbs contribute to an impulsion force 50±6% of the body mass, and the non-dominant limb 49±5%, while both upper limbs exert a impulse force that represent 98±9% of the body mass. Non-statistical significant differences confirm that the movement was executed in balance ($p=0.43$). The front foot reaches the surfboard with a force that represent 118±29% of the body mass, and the back foot with 36±14%. When both feet land, they apply a force on the surfboard that represents 153±35%. Statistical significant differences were observed between lower limbs ($p<0.001$).

Figure:



Caption: Pop-Up Movement - a) Force plates setup. b) Paddling simulation on the floor. c) Impulsion. d) Flight. e) Reach. f) Stabilization

Conclusion: It was possible identify some didactical (Fig. 1.b-f) and analytical (Fig.1.g.) phases of the Pop-Up movement, and analyze the forces in an independent way for each limb of the body, also verify the proportion of the force exerted on the surfboard during this process. The movement was divided in impulsion (Fig 1.c.), flight (Fig. 1.d.), reach (Fig. 1.e.), and stabilization (Fig. 1.f.) phases. We can conclude that the upper limbs needs to perform approximately the full body mass of force on the surfboard, to impulse the movement and stand-up. As well, when the body reaches the surfboard, the force applied represents about 150% of the body weight.

The force difference between the legs are expected, because when more force are applied in the front deck of the surfboard, the surfer increase the velocity on the wave, while if the force are applied on the back deck the board breaks. The low standard deviation shows values suggest that experienced recreational surfers show a similar way of performing the pop-up.

PO-0278

HUMAN GAIT USING LOCKED AND STANCE CONTROL MODE KNEE ANKLE FOOT ORTHOSES: OPTIMISING DATA ANALYSIS TECHNIQUES TO DETECT AND QUANTYIFY GAIT DEVIATIONS

James J. Skivington [1,*] Mairi Mackay [2] Andrew J Murphy [1] Karyn Ross [2] Craig Childs [1]

[1]Biomedical Engineering, [2]National Centre of Prosthetics and Orthotics, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Knee-Ankle-Foot Orthoses (KAFOs) potentially benefit a large range of patient populations with quadriceps weakness and knee instability. In the UK the most common prescribed is a locked-knee device, where the knee is locked in extension at all times, which have been shown to introduce secondary gait deviations, such as vaulting, hip hiking and circumduction. Stance control KAFOs, which lock the knee during stance but permit flexion during swing have been shown to reduce gait deviations as well as increase walking speed and efficiency.[1] The Gait Deviation Index (GDI)[2] is a metric distilled from a walking dataset to indicate the extent to which a person's gait deviates from a control. To our knowledge the GDI has not previously been demonstrated to quantify the effects of assistive devices, such as KAFOs. In addition, calculation of the GDI has often required substantial manual processing of data, which is time consuming and subject to human error.

The aims of this study were to conduct a comparison of walking biomechanics whilst using a KAFO in both locked and stance control modes, and also to develop a data processing utility to automatically calculate and report the Gait Deviation Index, as well as more traditional kinematic and spatial temporal data.

Methods: Sessions used a 12 camera Vicon B10 motion capture system installed in a Computer Assisted Rehabilitation Environment (Motek Medical CAREN extended suite) with a Becker Orthopaedic PreStride 2007, which can be set to both locked or stance control mode, and adjusted to fit the majority of participants. It is worn with sandals to accommodate the bulk of the device.

The participants were age 25±6.03 years and screened to ensure that they had no conditions which would affect the results or endanger them then provided with a 15 minute acclimatisation period to ensure correct knee operation.

Each person completed a 30s trial in the following randomised conditions walking at a self-selected speed:

- Own footwear – used to generate control group data for GDI calculations
- KAFO footwear – used as the normal gait condition to mitigate any deviations caused by the footwear
- Locked mode
- Stance control mode

The analysis tool was created using Microsoft Excel 2010 and Schwartz's GDI template.(2) The template allowed a single step's GDI to be calculated, but the developed tool allowed up to 15 steps of kinematic, spatial temporal and GDI data for both legs to be found.

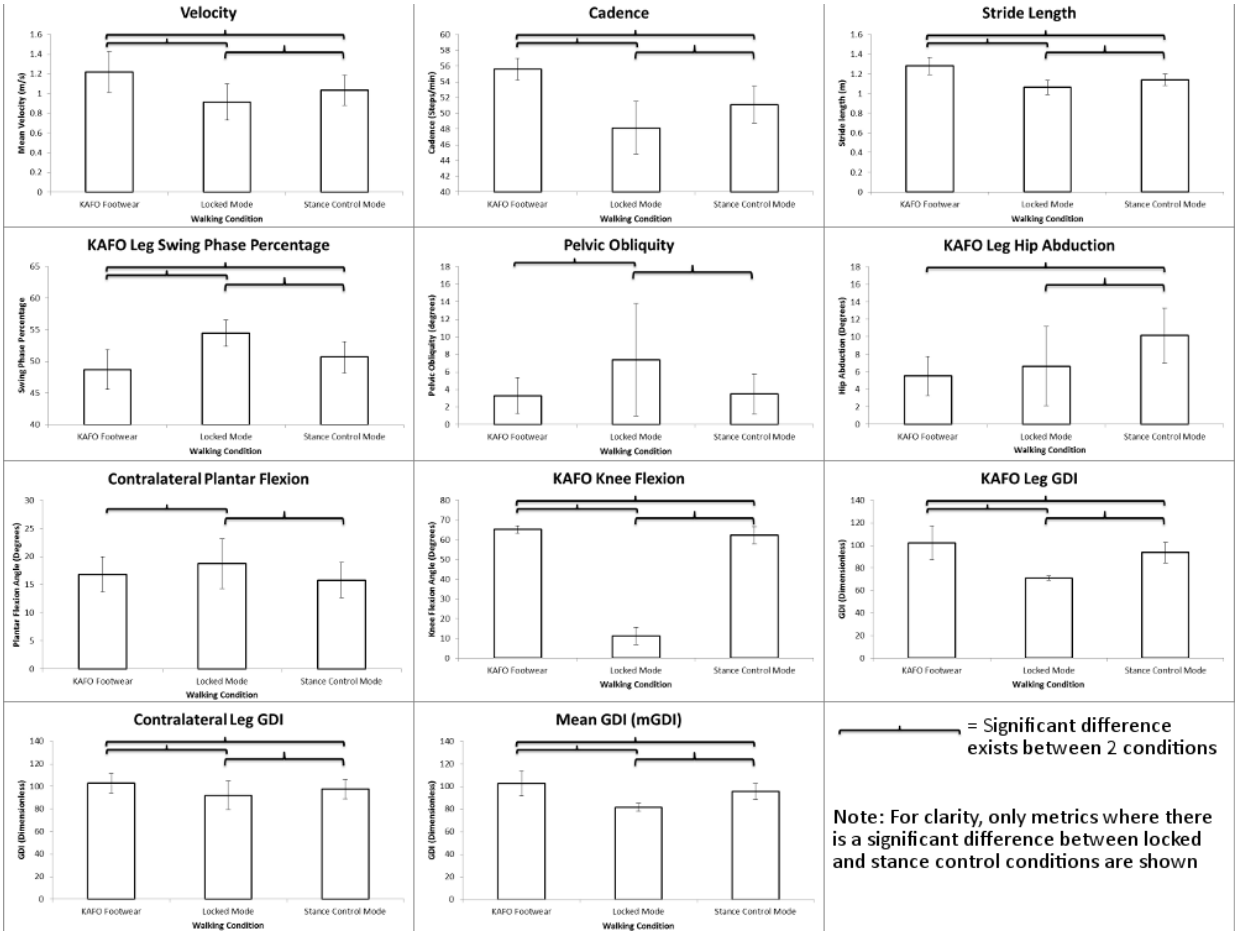
Heel velocity was used to calculate step and swing phase status - sensitivity adjustments were incorporated to mitigate heel movement during stance phase.

Steps with sample sizes outside of 0.5 std. dev. of the mean were excluded whilst valid steps were downsampled to ensure compatibility with the GDI calculator. This resulted in an output of a 16-metric analysis for each valid step. Results were subjected to a K-S test to determine distribution. Where data was normally distributed an ANOVARM was used to determine significance, whilst data which was non-parametric was subjected to a Wilcoxon Signed Ranks test.

Results: Fig 1 shows velocity, cadence and stride length increase when going from locked to stance control to normal modes. Davis[3] and McMillan[4] found increases from locked to stance whilst Zissimopoulos[5] reported increases from stance to normal modes. The reduction in KAFO leg swing phase from locked to stance was also observed by Davis. Contralateral plantar flexion (vaulting) and pelvic obliquity (hip hiking) decrease from locked to stance mode whilst KAFO leg hip abduction (circumduction) and knee flexion increases from locked to stance to normal modes. Zissimopoulos found a similar reduction in pelvic obliquity.

All GDI metrics increase from locked to stance to own footwear trials – showing an increase as joint restriction decreases. This presents similar findings to Molloy [6] who used GDI to evaluate Cerebral Palsy patients and found a linear relationship between the GDI and the patient's GMFCS.

Figure:



Caption: Fig 1: Trial Data

Conclusion: Overall, the device presents improved spatial temporal and kinematic performance in stance mode compared to locked mode. There is, however, a reduction in performance from the normal trials to stance control mode, showing there are still gait deviations present.

The GDI score shows a linear relationship with the mode of the device – as the device becomes more restrictive the GDI decreases. This shows that the GDI may be considered a useful tool for quantifying the effect of devices.

The author found that the tool created allows processing to be cut down from 30-40 minutes per participant to 1-2 minutes. This presents a large potential time saving, easier access and lower likelihood for error.

SPATIAL VARIABILITY IN NORMAL OVERGROUND GAIT

Christoph Mickel [1,*] Gerrit Kollegger [2] Dietmar Schmidtbleicher [3]

[1]Exercise Physiology and Human Movement Science, Institute for Sport Science, Frankfurt, [2]Institute for Sport Science, Darmstadt, [3]Exercise Physiology and Human Movement Scinece, Institute for Sports Science, Frankfurt am Main, Germany

Introduction and Objectives: There are plenty of measures in gait like step width, step length and so forth [1] and all of those are useful also for looking at the variability, but until now there is no common way to determine the spatial variability in the three dimensional space.

Methods: 48 students of the Institute for Sports Sciences (height 178 cm ± 11,3, weight 72,1 kg ± 12, age 23,5 years ± 3,92) that had no acute or chronic lesions or diseases of the lower extremities carried four 3D accelerometers (Analog Devices ADXL 326), which were mounted to the distal end of Os metatarsale III and below the Malleolus lateralis of each foot. Sampling frequency was set to 2000 Hz. Subjects were instructed to walk at their preferred walking speed for consecutive 20 to 25 minutes. Two double-photoelectric barriers measured locomotion velocity several times during the trial. Average locomotion velocity for the group was 1,57 m / s ± 0,16 with an average SD for the single subject of 0,02 m / s.

After separating the accelerometer time-series into stride intervals, stance, swing and double-support times the data was normalized in time (2000 data points) and a point-to-point ensemble-average-curve was determined for each subject in each of the three axis. Therefore the standard deviation (SD) was calculated for each point in time. To obtain the total amount of variability at every point in time the SDs of the different axis were multiplied. The result is a variability cuboid. From these volumes the mean value and SD for the stance, swing and double-support-times was calculated. This procedure was performed for both feet. The data was tested for normal distribution with the Shapiro-Wilk-test. As this condition was not fulfilled the Friedman's test with post-hoc Wilcoxon test was applied ($p < 0,05$).

Results: Friedman's test showed significant (p=0,000) differences between the different gait phases for each foot. The post-hoc Wilcoxon-tests showed significant differences between the variability of stance and swing (p=0,000), stance and double-support-time (p=0,000) and swing and double-support-time (p=0,000). The applied Wilcoxon-tests between each phases right with left showed no significant differences (stance right vs. stance left: p=0,713; swing right vs. swing left: p=0,778; double-support-time right vs. double-support-time left: p=0,544).

Conclusion: The significant differences between swing and the other two phases may be explained through the restriction of the movement trajectory in the vertical direction by the ground and the anatomic-morphological and mechanical limitations [2, 3]. The significant difference between stance and double-support-time may be lead back to the fact that in double-support-time an even stronger stability exists since there is only very limited time to shift the weight from one leg to the other. The safety margin may be very small to accomplish that task. Further studies are necessary to clarify this finding.

Table:

Parameter	foot	N	Average	Min	Max	SD
V Stance	right	41	144443,3	36348,9	1423491,6	217489,9

3D SHOULDER ROTATION USING ISB EULER ANGLE ALGORITHMS

Simon Thwaites [1] Paul Grimshaw [1,*] Michael Cole [2] Merilyn Lock [3]

[1]School of Mechanical Engineering , University of Adelaide , Adelaide , [2]School of Exercise Science, Australian Catholic University , Brisbane , [3]School of Medical Sciences , University of Adelaide , Adelaide , Australia

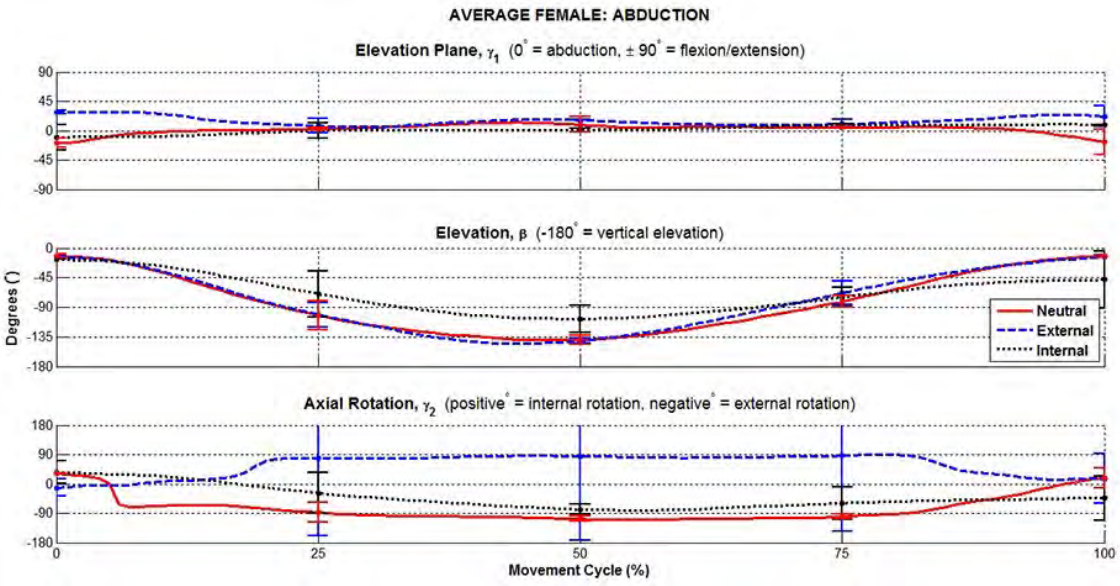
Introduction and Objectives: Describing anatomical movements easily is a problem for clinicians, scientists and engineers. Shoulder girdle movements are complex and promote a high degree of difficulty for analysis. This can be attributed to the shoulder's multiple articulating segments. Comprehensive evaluation of the shoulder must take these articulations into consideration. The International Society of Biomechanics (ISB) developed an approach utilizing sequence-dependent Euler angles to describe anatomical motion (Wu et al 2005). This method orientates a given anatomical segment's local coordinate system (LCS) with reference to another segment's LCS. However, insufficient bony landmarks exist on the humerus to define its LCS (i.e. the origin of which is at the glenohumeral (GH) joint rotation centre). The position of the GH joint rotation centre (GH-r) is required to define the longitudinal, y-axis of the humerus LCS. Hence, the position of the GH-r requires estimation, as it is not a bony landmark (Van der Helm 1996; Meskers et al 1998). The LCSs of the humerus and thorax combine to construct the thoracohumeral joint coordinate system (JCS) such that motion of the humerus is defined in a Y-X′-Y″ rotation sequence. For the thoracohumeral JCS, these rotations are defined as *Plane of Elevation*, *Elevation* and *Axial Rotation*, respectively. Currently, the manner in which motion data is collected and presented is at the discretion of the researcher. This lack standardization inhibits comparison of results between studies. Adopting a standard would aid assessment of shoulder injuries and degeneration, inform rehabilitation techniques and have implications for robotic applications (Rosso et al 2013). This study modeled the shoulder joint throughout simple and complex movement patterns, via an anatomical marker-based approach (ISB recommendations). The study also assessed the reliability and effectiveness of this approach in describing shoulder motion with a focus on ease of clinical interpretation.

Methods: Testing was conducted with a 16-camera motion capture system (OptiTrack, Corvallis, USA, 100Hz) and AMASS software (C-Motion Inc., Germantown, Maryland, USA). Twenty-two optoreflective markers (5 markers to define the GH-r centre) were placed on ISB-specified bony landmarks. Data were post-processed in AMASS and then imported into MATLAB (The MathWorks, Natick, MA, USA) for further processing. The approach was evaluated on one subject by analyzing three clinical range of motion (ROM) movements (humeral abduction, flexion and extension), forming the foundation for the development of the MATLAB code. This was then extended to analyze six subjects (2 female and 4 male) and five clinical ROM movements (humeral abduction (AB), flexion (FL), extension (EX), horizontal flexion (HF) and horizontal extension (HE)) at three different orientations (full external (EXT), full internal (INT) and neutral (N) orientations; 15 ROM tests in total). An easily repeatable and complex movement pattern (throwing) was also analyzed.

Results: Time series plots of the three Euler angles required to describe thoracohumeral rotation for left humeral AB, FL, EX HF and HE are presented at all three orientations (EXT, INT and N). This subplot sequence is consistent with the order of the Euler angle rotations according to ISB guidelines (Wu et al 2005), i.e., *Plane of Elevation* ($\gamma h-1$), *Elevation*

(βh), and *Axial Rotation* (γh−2). The γh−1, βh, and γh−2 values between the start and end of movement were mapped to 0% and 100%. This allowed for averaging and comparison for a given ROM between the male and female subjects. Similarly, each subject's dominant (right) shoulder motion was plotted for the throws. Mean and standard deviation values are presented at 0, 25, 50, 75, and 100% of the movement cycle for the female and male groups and statistical significance of any differences between the groups was assessed. Figure 1 shows the results for the abduction ROM tests for the female subjects (n=2).

Figure:



Caption: Fig 1 Abduction ROM test for n=2 female subjects

Conclusion: These movements were described using guidelines proposed by the ISB. Thoracohumeral rotation was decomposed into three sequence-dependent Euler angles via well-known vector mathematics techniques and Rodrigues' rotation formula. A mathematical regression based on the location of five bony landmarks about the scapula was incorporated into the analysis in order to define the humeral coordinate system. It is concluded that the approach would provide a quantitative assessment of mobility and identification of underlying causes of movement disability. However, further work needs to be conducted in order to provide a clinically meaningful assessment of *Axial Rotation* of the humerus.

PO-0281

EFFECT OF ALTERED WALKING SURFACE AND VISUAL CONDITION ON SELECTED KINEMATIC AND KINETIC GAIT PARAMETERS OF YOUNG HEALTHY WOMEN AND WOMEN WITH ANKLE SPRAIN.

Raghad Mimar [1,*] Roya Hoveizavi [2] Hadi Mohammadi [1]

[1]Biomedical Engineering, University of British Columbia, Kelowna, Canada, [2]Physical Education and sport sciences, Kharazmi University, Tehran, Iran, Islamic Republic Of

Introduction and Objectives: Maintaining balance while walking involves coordination of response from multiple sensory systems including the vestibular, somatosensory, and visual systems. The objective of this study is to investigate the effect of altered walking surface, and consequently, the altered plantar proprioception on selected kinematic and kinetic gait parameters of both young healthy women and women with ankle sprain.

Methods: 22 young healthy women (age range?) and women with ankle sprain participated in this study. Subjects performed 3 trials of walking on 6 different conditions: natural surface with natural light, natural surface with low light, soft surface with natural light, soft surface with low light, irregular surface with natural light, and irregular surface with low light. Gait timing, stride length, gait velocity, cadence, whole body acceleration and both vertical and shear forces were measured from a two-dimensional motion analysis system and force platform. For data analysis, MATLAB (version 6.5) and SPSS (version 21) were implemented in this study.

Results: Results showed no significant difference between the normal and ankle sprain group in all conditions. However, the ankle sprain group showed less mean value and greater standard deviation (SD) in force and acceleration. However, within groups, there was a significant (word missing?) within subject effect of surface on walking velocity (only between soft and irregular surfaces, sig=0.036), strongly on vertical and A/P shear whole body acceleration (between all three surfaces, sig=0.000), force of the loading response phase (sig= 0.002) and maximum and minimum A/P shear forces (sig= 0.000). Also, vision had a significant effect on whole body acceleration of the loading response phase (sig=0.000). The combined effect of surface and vision was significant only on the whole body acceleration of the loading response phase (sig=0.000), (Tbl. 1)

Conclusion: It is concluded that surfaces (especially soft surfaces) have greater effect on walking kinematics and also, soft surfaces have greater stimulation on proprioception. Walking on irregular surfaces also needs greater propulsive shear force, which could result in faster muscular fatigue. With the exception of the acceleration of loading response phase, the low light condition had no significant effect on steady state walking, which appears to be one of the restrictions of this investigation.

Table:

Effect of surface and vision (sig)	Effect of vision (sig)	Effect of surface (sig)	Parameter
0.955	0.900	**0.036***	**Walking velocity**
0.000*	**0.000***	**0.000***	**Vertical whole body acceleration of early stance**
0.540	0.276	**0.002***	**Vertical whole body acceleration of late stance**
0.664	0.341	**0.000***	**Maximum A/P Shear acceleration**
0.897	0.987	**0.000***	**Minimum A/P Shear acceleration**
0.540	0.295	**0.002***	**Vertical force of late stance**
0.600	0.341	**0.000***	**Maximum A/P Shear force**
0.890	0.975	**0.000***	**Minimum A/P Shear force**

MEASUREMENT OF 3D FOOT DEFORMATION DURING HUMAN WALKING BY DIGITAL IMAGE CORRELATION METHOD

Kohta Ito [1,*] Ikumi Fujiwara [1] Koh Hosoda [2] Takeo Nagura [3] Naomichi Ogihara [1]

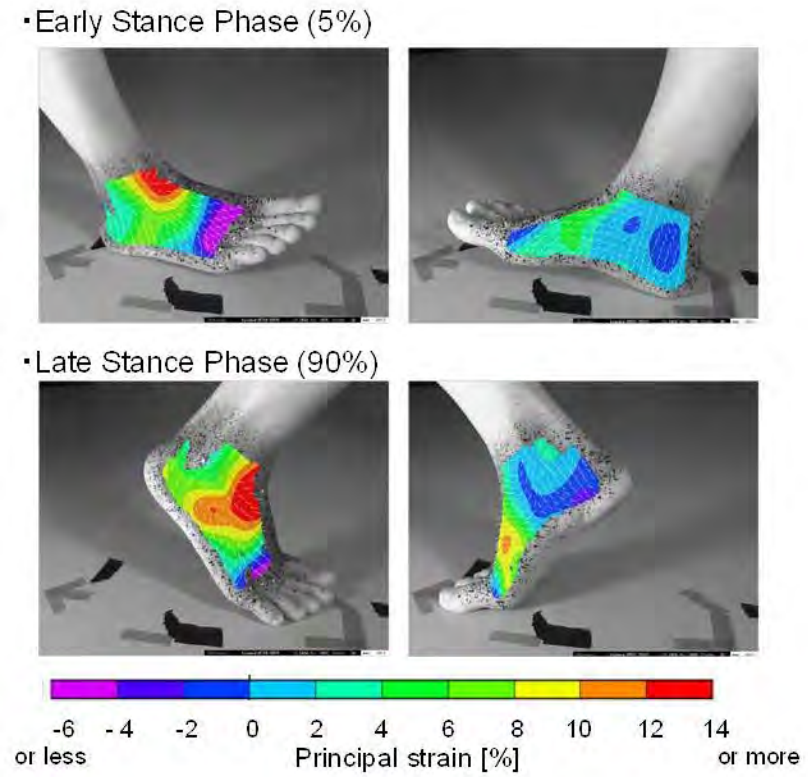
[1]Department of Mechanical Engineering, Keio University, Kanagawa, [2]Graduate School of Engineering Science, Osaka University, Toyonaka, [3]School of Medicine, Keio University, Tokyo, Japan

Introduction and Objectives: Human walking is a mechanical phenomenon to move the centre of body mass forward without falling by appropriately generating the ground reaction forces by the feet. Detailed understanding of the deformation of the foot during walking is important for elucidating how the structure of the human foot facilitates appropriate mechanical interaction with the ground in generation of robust bipedal walking. However, the nature and degree of foot deformation during human walking have not been fully investigated. In this study, we aimed to clarify the three-dimensional (3D) deformation of the human foot during bipedal walking by means of digital image correlation (DIC) method, an optical method to measure 3D deformation of an object surface by using the stereo-triangulation and the image correlation of speckle pattern on the object surface [1].

Methods: Two adult male participants were asked to walk along a walkway at a self-selected speed and the surface of the right foot during the stance phase (from heel-contact to toe-off) were filmed at 1000Hz using two synchronized high speed cameras (MEMRECAM GX-3, NAC Image Technology, Japan) with a resolution of 1280 x 1024 pixels. Dorsolateral and medial surfaces were filmed separately. The right foot was sprayed with aqueous black ink to draw the speckle pattern on the distribution of the magnitudes and directions of the principal strain on the surface of the foot in the stance phase. The skin strain distribution was calculated by taking the foot shape at the middle of the stance phase as the reference shape configuration. Digital image correlation method software Vic-3D (Correlated Solutions, Columbia, SC, USA) was used for quantification of the foot deformation.

Results: The figure represents the principal strain distribution of the foot during stance phase. Our results demonstrated that in the early stance phase, the dorsal surface around the ankle was stretched and that around the metatarsophalangeal joint was contracted in the anteroposterior direction due to the plantarflexion and dorsiflexion, respectively. In the late stance phase, the lateral surface of the rear foot is stretched, while the medial surface is contracted, both in dorsopalmar direction, suggesting that the calcaneus was inverted with respect to the talus. At the same time, the lateral surface of the midfoot was stretched in the anteroposterior direction, suggesting the pronation of the forefoot. Inversion of the heel and pronation of the forefoot produce the rigid structure of the foot (locking mechanism [2]) for generating propulsive force in the late stance.

Figure:



Caption: Principal strain distribution of the foot during walking (Left: dorsolateral, Right: medial)

Conclusion: The present study demonstrated that the DIC method can be successfully applied to capture and quantify the 3D deformation during bipedal walking. Although this methodology has some limitations and must be undergone further evaluation, the present framework may serve as an effective tool for understanding the morphofunctional roles of the human foot structure during walking.

JOINT BIOMECHANICS AND BALANCE ISSUES DURING COMMON REHABILITAITON EXERCISES IN OBESE FEMALES

Bhupinder Singh [1,*] Ashley Artsdalen [1] H. John Yack [1]

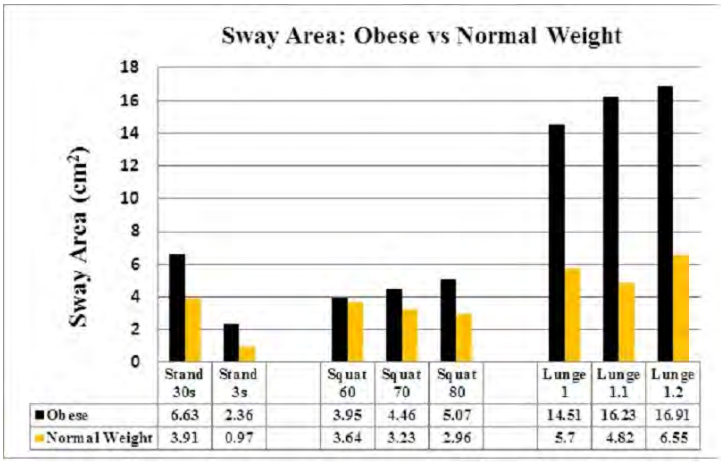
[1]Physical Therapy, California State University , Fresno, United States

Introduction and Objectives: Obese individuals may have difficulty performing basic rehabilitation exercises like squat and lunge. Balance and adipose tissue restriction, are major issues for obese individuals, which could have implications on joint biomechanics. Despite potential for biomechanical differences from normal weight subjects, the influence of obesity on the performance of squat and lunge has not been documented. The purpose of this study was to analyze and compare the joint biomechanics of obese females, as measured by joint moments and balance, as measured by sway area of center of pressure (COP) while performing squat and lunge exercises. It is hypothesized that obese females will have higher joint moments and poorer balance control than their normal weight counterparts, and that as the difficulty of the exercises increase, the increase in joint moments and balance control deficits will be more apparent.

Methods: Ten obese (BMI > 30 kg/m2) females 37.4 ± 3.7 years, BMI 39.2 ± 3.7 kg/m2 and ten normal weight (BMI

Results: For the squat, hip and knee extensor moments in obese females were not different than normal weight females for all three levels. However, ankle extensor moments were higher in obese females (p=0.04). The support moment was higher in obese females for squat 70 (p=0.03) and squat 80 (p=0.01), but not different for squat 60 (p=0.07) (Table 1). Sway area was not different between obese and normal weight females for squat 60 (p=0.62) squat 70 (p=0.16) and squat 80 (p=0.11) (Figure 1). There was no within group differences for squat 60, 70 and 80. For the lunge, hip extensor moments were greater in obese females for level 1, 1.1 and 1.2 (p-values: 0.004, 0.003 and 0.007 respectively). Knee and ankle extensor moments were not different (Table1). Support moments showed an overall group effect between obese and normal weight subjects (p=0.01). Sway area was higher for obese females for all three levels of lunge, lunge 1 (p=0.004), lunge 1.1 (p=0.002) and lunge 1.2 (p=0.001). The lunge had greater sway area as compared to standing as well as squat activities (p

Figure:



Caption: Mean sway area for standing eyes open 30 s, standing 3 s, squat and lunge levels. The asterisk (*) shows significant differences between activities ($p<0.05$).

Conclusion: The lunge activity was more challenging for obese females than squatting and standing, as shown by greater sway area and hip joint moments. It could be argued that the excess adipose tissue in obese subjects caused an increase in hip moment. When compared to standing 3 s, squat and lunge have greater sway area, although significant differences are only seen for lunge, which could be attributed to the greater base of support and more effort needed to stabilize the mediolateral shift of the trunk in obese individuals. There were no differences in the three squat depths, indicating that squat may be a better exercise choice for obese individuals with fall risk or joint pathologies like hip arthritis. To conclude, identifying the underlying biomechanical issues and the strategies used by obese individuals during these common rehabilitation exercises can provide a rationale to set different recommendations for the obese population.

Table:

Moment(Nm/kg)		**Squat 60**	**Squat 70**	**Squat 80**	**Lunge 1**	**Lunge 1.1**	**Lunge 1.2**

PO-0284

EFFECT OF CRYOTHERAPY ON ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE: A RANDOMIZED CLINICAL TRIAL

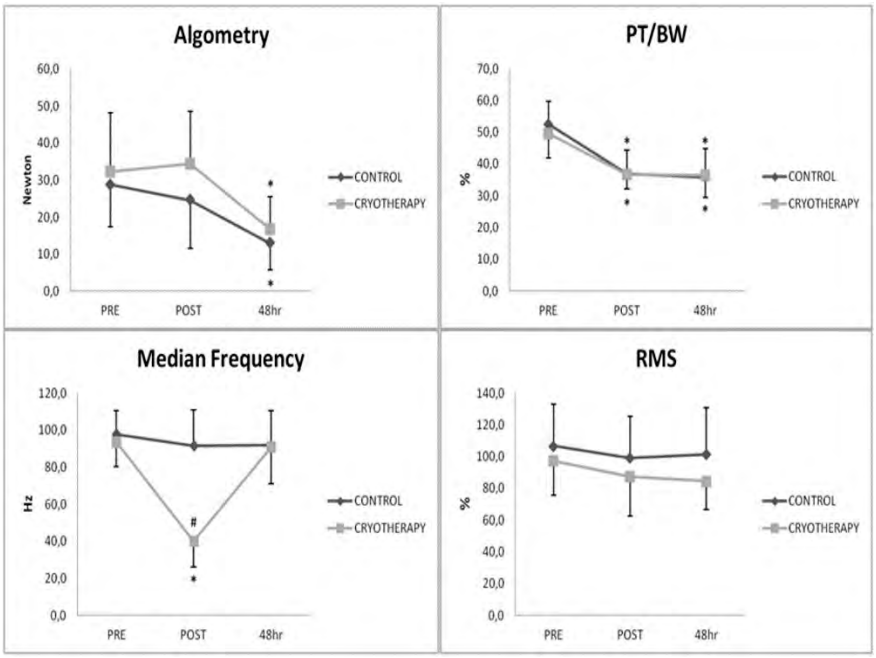
Liane B. Macedo [1,*] Caio Lins [2] Daniel Borges [1] Jamilson Brasileiro [2]

[1]Department of Physiotherapy, [2]Universidade Federal do Rio Grande do Norte, Natal, Brazil

Introduction and Objectives: Exercise-induced muscle damage provokes the installation of an inflammatory process that results in a sensation of pain and discomfort in individuals [1]. Recently cryotherapy has been used in many sports as a strategy to recover from exercise-induced muscle damage, such as after training or competition [2, 3]. Its effects on damaged tissue help relieve pain, inflammation and oedema, since it provokes local vasoconstriction, which reduces capillary, lymphatic and cell permeability, lowering inflammatory response and oedema associated to trauma [4,5]. It has been observed that cooling decreases secondary hypoxia, with a consequent decline in muscle necrosis. Furthermore, deceleration of cell metabolism and nerve conduction velocity would occur, limiting injury secondary to lesion and pain [5]. This positive effects caused by cooling, individuals would manage to continue their training, with no decrease in performance, in the days following injury [4]. However, are necessary more studies to evaluate these effects on muscle recovery. Thus, the present study aims to assess the effect of cryotherapy on eccentric exercise-induced muscle damage.
Methods: This is a randomised clinical trial composed of 40 women (22.8±2.2 years). Participants were randomly divided into two groups: control group and cryotherapy. Both groups underwent three assessments: pre, immediately after and 48 hours after intervention, all composed of algometry, dynamometry (peak torque normalized by body weight) and electromyography (root mean square and median frequency). After initial assessment, all the participants were submitted to an eccentric exercise protocol on an isokinetic dynamometer (2x10 maximum eccentric contractions of non-dominant elbow flexors at 60°/s). Next, participants were submitted to the interventions: the control group did not undergo any intervention and remained at rest for 25 minutes; to cryotherapy group a 1kg ice pack was strapped over the entire brachial biceps muscle and adjacent muscles of the arm under study using a bandage. Application lasted 25 minutes and a digital thermometer with interface was used to measure cutaneous temperature and ensure cooling level [6]. After the interventions each subject underwent two assessments: Immediately (post) and 48 hours after the interventions, identical to the first assessment. SPSS for Windows (version 20.0) was used for all statistical analyses. A test t was used to investigate baseline differences between groups. A mixed design ANOVA (3x2) was used to investigate changes in algometry, peak torque normalised for body weight, median frequency and RMS with one between-subjects variable, *group*, with two levels and one within-subject variable, *time*, with three levels. The effect of group, time, and group by time interactions were tested. When the assumption of sphericity was violated, significance was adjusted using the Greenhouse-Geisser method. When the effect of test was significant, the analysis using the multiple comparison Bonferroni post-hoc test was applied. A 5% significance level was used ($p < 0.05$).
Results: No initial differences in anthropometric measures or variables analysed were observed between the groups. In relation to algometry, a significant difference was observed for the control and cryotherapy groups, with a statistical difference at 48hr compared to pre and immediate post ($p<0.01$). However, no intergroup difference was observed

(p=0.15). Analysis of peak torque normalised for body weight had altered values for both groups, demonstrating a difference at pre to immediate post and 48hr (p<0.01), but no intergroup difference (p=0.77). Analysis of electromyographic variables shows that median frequency was a significant difference in cryotherapy group, demonstrating an intragroup difference at post to pre and 48hr (p<0.01) and intergroup difference between post (p<0.01), probably due to reduction in nerve conduction velocity from cooling [7]. The electromyographic amplitude revealed no significant pre, immediate post and 48hr difference after intervention in the two groups assessed for RMS (p>0.05), or any intergroup variation (p=0.76) (Figure 1).

Figure:



Caption: Figure 1. Means of algometry, peak torque normalized by body weight (PT/BW),median frequency and root mean square (RMS) to control and cryotherapy groups. * indicates significant change compared to baseline values. # indicates significant change between groups.

Conclusion: The results of the present study suggest that cryotherapy do not interfere in the response to eccentric exercise-induced muscle damage to any variable analysed.

PO-0285

NONINVASIVE MUSCLE FORCE EVALUATION OF THE PSOAS MAJOR DURING ISOMETRIC HIP FLEXION

Hiroshige Tateuchi [1,*] Yuta Kondo [1] Tadao Tsuboyama [1] Noriaki Ichihashi [1]

[1] Kyoto University, Kyoto, Japan

Introduction and Objectives: The psoas major (PM) has an important role in motion and stabilization of the hip joint and lumbar spine. Activity of the PM can be recorded using an intramuscular fine-wire electrode since the muscle is situated deeply. However, such invasive evaluation is difficult for clinical application. Shear-wave elastography is a reliable noninvasive technique for evaluating individual muscle force by measuring shear elastic modulus. Previous studies have shown that the relationship between torque and shear elastic modulus of the muscle differs according to the muscle [1]. The purpose of this study was to determine the relationship between exerted muscle force and shear elastic modulus of the PM using shear-wave elastography.

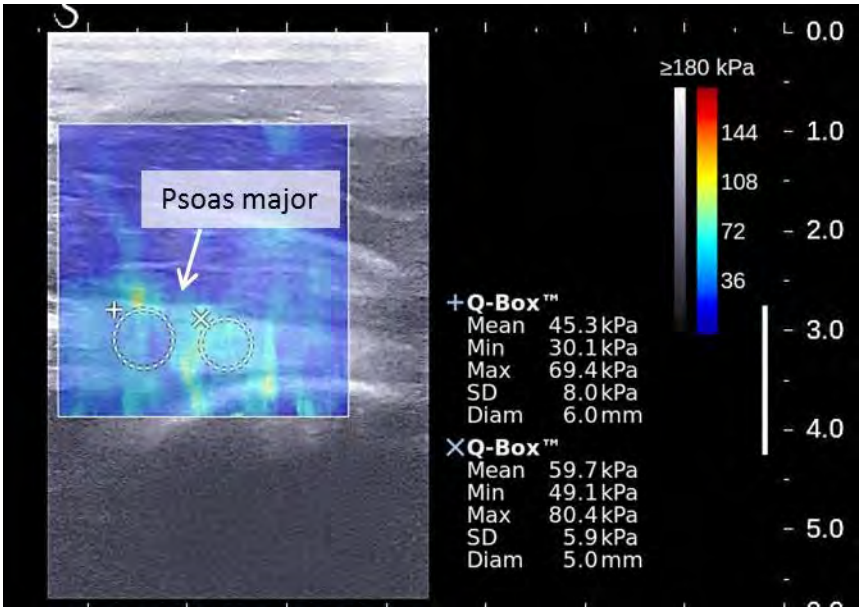
Methods: Nineteen healthy men (mean age, 22.1 ± 1.5 years) participated in this study. All subjects provided informed consent, and the protocol was approved by the local ethics committee. Participants sat on a lifting chair with hips flexed at 45°. The pelvis was fixed by a belt to prevent pelvic posterior tilting. Prior to data collection, maximum isometric strength of hip flexion was measured in above-mentioned posture. Shear elastic modulus of the PM was measured just distal to the inguinal ligament using shear-wave elastography (Aixplorer; Supersonic Imagine, Aix-en-Provence, France). The PM was identified by using B-mode imaging, and the transducer was placed longitudinally with respect to the direction of the muscle fibers. Participants were instructed to perform isometric hip flexion at 0%, 10%, 20%, and 30% of maximum strength, keeping the foot off the floor (0% represents active hip flexion at 45° without external load). Measurement at 40% was excluded from analysis because maintaining stable isometric contraction was difficult. The examiner confirmed the exerted force using the force sensor and a screen on which the force was displayed in real time. Two regions of interest for measurement of shear elastic modulus were set on the PM, and their mean was calculated. All measurements were performed three times, and the mean shear elastic modulus value was used in the analysis. The conditions (0%>30%) were measured in random order. For shear elastic modulus values of the PM, a paired t test with Shaffer correction for multiple comparisons was used to determine differences among rest and 0% to 30% conditions. A P value of <0.05 was considered statistically significant.

Results: Shear elastic modulus of the PM increased significantly in 0%, 10%, 20%, and 30% conditions compared with that at rest. Furthermore, shear elastic modulus of the PM increased significantly in 10%, 20%, and 30% conditions compared with that in the 0% condition. However, there were no significant differences among 10%, 20%, and 30% conditions. The external load measured 5 cm proximal to the patella in the 10% condition was 4.4 ± 1.0 kg.

Our findings indicate that shear elastic modulus of the PM increases with an increase in muscle force within a limit of 10% of maximum strength. Our previous study showed that muscle thickness of the PM did not change with an increase in muscle force. Therefore, the method used in this study would be useful for evaluating PM function during light-load motion in the patients with muscle weakness. However, the results suggest that muscle force of the PM at more than 10% of

maximum strength cannot be evaluated because of a technical limitation. Change in shear elastic modulus of the PM at different hip joint angles still needs to be investigated.

Figure:



Caption: A typical example of shear elastic modulus measurement at the psoas major. Young's modulus of the 2 regions of interest (Q-box), arranged in the psoas major, was calculated. The shear elastic modulus was obtained by dividing Young's modulus by 3.

Conclusion: Muscle force of the PM during isometric hip flexion can be evaluated using shear-wave elastography within a limit of 10% of maximum strength (i.e., hip flexion with up to an approximately 4.4-kg load).

None of the authors have any conflicts of interest associated with this study.

Table: Shear elastic modulus (kPa) of the psoas major

PO-0286

DEVELOPMENT OF THE PORCINE KNEE MODEL FOR PRE-CLINICAL TRIBOLOGICAL ASSESSMENT OF CARTILAGE REPAIR INTERVENTIONS

Aiqin Liu [1,*] Louise Jennings [1] Eileen Ingham [2] John Fisher [1]

[1]School of Mechanical Engineering, [2]School of Biomedical Sciences, Institute of Medical and Biological Engineering, University of Leeds, Leeds, United Kingdom

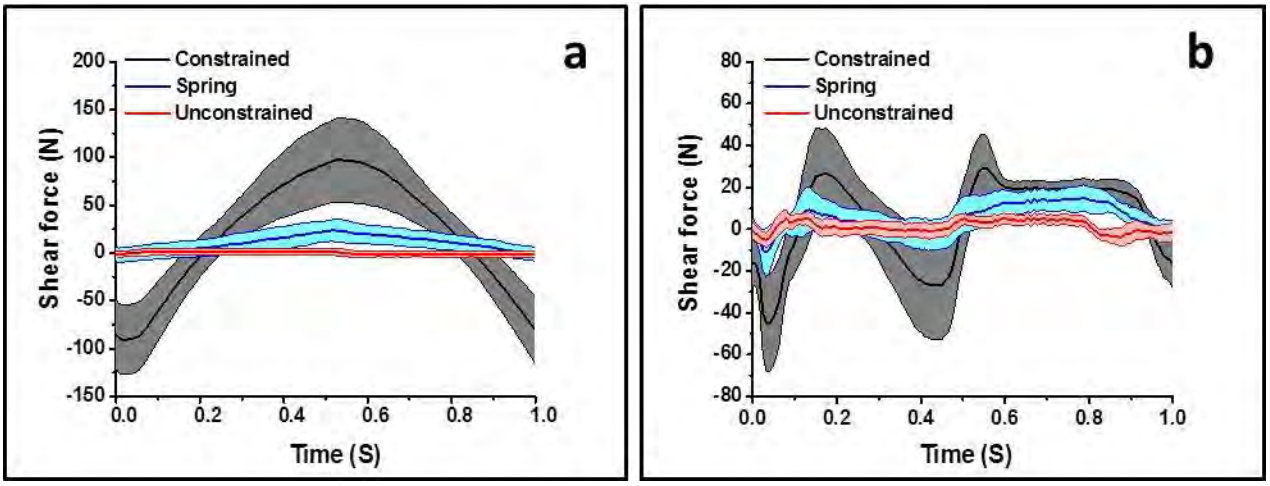
Introduction and Objectives: To date, the success of early-stage cartilage repair interventions in the knee has been constrained by a lack of biomechanical and biological consideration in the design of the therapeutic interventions. This stems from an inadequate understanding of functional cartilage biotribology in the natural knee joint. Therefore, the aim of this study was to develop and validate a porcine knee model using a whole joint knee simulator investigating tribological and biomechanical properties of the natural knee, which could then be used to assess the restorative function and tribology of cartilage repair interventions before they are assessed *in vivo*.

Methods: Porcine knee joints (N = 6) were dissected by removing soft tissues leaving only the cartilage and meniscus in place, and mounted into a single station knee joint simulator (Simulator Solutions). The tribological behaviour in terms of frictional shear force between the femur and tibia was ascertained under 3 conditions, each of which induced different frictional sliding and rolling behaviours. These conditions were achieved through varying the constraint in the anterior-posterior (AP) axis as follows: 1) Sliding condition, which was created by constraining the tibial AP carriage; 2) Rolling condition, which was created by decoupling the tibial AP carriage (unconstrained); 3) A combination of sliding and rolling conditions were created by the incorporation of springs (K=2.69 $N.mm^{-1}$). The mean frictional shear force with 95% confidence limits was determined under the three AP conditions.

Results: As shown in Fig. 1a, under 'simple input' kinematic conditions, the AP constrained condition displayed increased shear force with increased flexion angle, resulting in a triangular shear force profile with a peak anterior value of 97.4±43.8 N at maximum flexion. The shear force under spring condition showed a smaller magnitude triangular wave pattern than constrained condition with a peak value of 23.4±11.8 N at maximum flexion. A shear force profile with constant low values (1.6±3.0N) was observed under AP unconstrained condition.

During a clinically relevant gait cycle, the AP constrained condition caused a higher shear force response with a range from 45.1±22.8 N (at 0.04 s) posteriorly to 29.2±15.8 N (at 0.55 s) anteriorly, compared to the shear force values ranging from 11.2±11.6 N (at 0.03 s) posteriorly to 14.7± 6.4 N (at 0.79s) anteriorly under spring condition (Fig. 4b). The spring condition showed increased shear force values compared to the AP unconstrained condition, specifically during swing phase of the gait cycle (in the region 0.62 s-0.8 s).

Figure:



Caption: Fig. 1. Average shear force of porcine knee joints (n=6) testing under a) simple profile with a constant load and flexion/extension only and b) complex profile inputs based on a standard gait cycle and appropriately scaled for a porcine joint. The grey, blue and red regions indicate 95% CI of the mean of shear force under AP constrained, spring and AP unconstrained conditions.

Conclusion: The shear force measurements under both simple input profile and clinically relevant gait cycle input showed higher values under the AP constrained condition where sliding motion occurred, compared to the AP unconstrained condition where rolling motion occurred. The results indicated that the in vitro simulation model was able to simulate and measure different tribological behaviours when the femoral and tibial bearing was entrained to slide or/and roll. Therefore, the porcine knee model showed the potential capability to investigate the effect of knee structural, biomechanical and kinematic changes, on the tribological function of different cartilage substitution therapies.

PO-0287

THE MAGNITUDE OF STRETCH-INDUCED FORCE ENHANCEMENT FOLLOWING SHORTENING IS TIME-DEPENDENT

Rafael Fortuna [1,*] Geoffrey A. Power [1] Walter Herzog [1]

[1] Faculty of Kinesiology, university of Calgary, Calgary, Canada

Introduction and Objectives: Force production is influenced by history-dependent properties of muscle. Following an active lengthening or shortening contraction, the steady-state isometric force is distinctly different than a purely isometric contraction at the same muscle length and activation level[1]. These properties are referred to as residual force enhancement (FE) following active lengthening and force depression (FD) following active shortening. Force enhancement and FD properties have been observed at all structural levels[1,2] and have also been found in human voluntary and electrically stimulated muscles[2]. However, the detailed mechanisms causing FE and FD remain unknown. During functional tasks, muscles usually undergo shortening-stretching cycles (SSCs) while activated. It has been shown that active shortening preceding a stretch reduces the stretch-induced FE, but this reduction disappears if shortening and stretch are separated by sufficient time in frog single muscle fibers[3]. However, it is unclear whether this time-dependent effect is present in intact human muscles, and thus might play a role in every day movements. The purpose of this study was to evaluate the effect of time between active shortening and lengthening on the stretch-induced FE in the adductor pollicis of healthy young adults.

Methods: Twelve healthy male participants (age: 28±5 years; height: 180±6cm; weight: 75±5kg) gave free written informed consent to participate in this study. The left forearm was placed in a custom-designed dynamometer to assess thumb adduction forces[4]. Full thumb adduction was defined as 0° and abduction angles were defined as positive up to 30°. The adductor pollicis was electrically stimulated at a frequency of 50Hz via the ulnar nerve with a current intensity that produced 50-60% of each subject's maximum voluntary force. First, FD was determined by shortening the muscle at an angular velocity of 60°/s from 30° to 0° and comparing the steady-state isometric force following shortening to the corresponding purely isometric force. Next, three shortening-stretching cycles were randomized and performed with intervals of 0s (SSC_0s), 0.5s (SSC_0.5s), and 1s (SSC_1s) between the shortening and the stretching phase. Shortening and stretching were performed at an angular velocity of 60°/s and ranged from 0° to 30° and from 30° to 0°, respectively. Lastly, FE was determined using active stretching of the muscle at 60°/s from 0 to 30°. To minimize fatigue, a 5min interval was given between consecutive contractions. Each contraction was preceded by an isometric reference contraction (Ref) at the corresponding final thumb angle. The magnitude of FD (SSC_0s/0.5s/1s), and for FE were normalized relative to the corresponding isometric reference contractions. A repeated measures ANOVA was performed for comparisons between the different contractions with $\alpha<0.05$. When significance was observed, a Bonferroni post-hoc test was performed to identify differences.

Results: FD following active shortening was ~22% (result not shown), and FE following active stretching was ~20%. When zero (SSC_0s) and half a second time intervals (SSC_0.5s) were given between shortening and stretch, FE was significantly reduced to ~10 and 11%, respectively. However, when a one second interval (SSC_1s) was given, the effect

of shortening on the stretch-induced FE was abolished and FE was similar to the FE measured without shortening preceding the stretch (Fig. 1).

Figure:

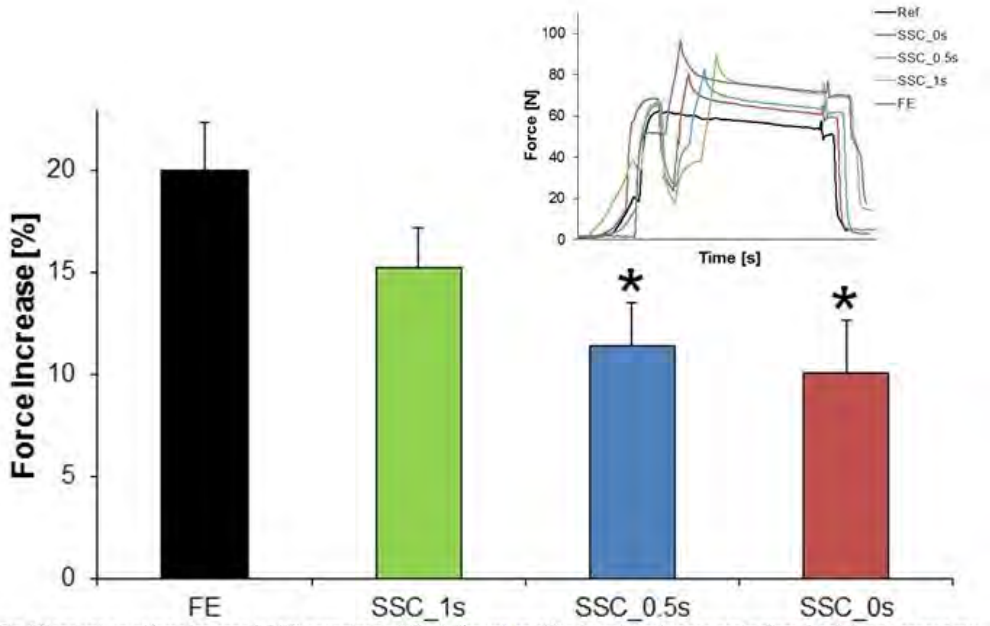

Fig 1 Mean values of force increase (+/-SE) normalized relative to the values of the isometric reference contractions. Inset: Seven second raw force traces for the different experimental conditions. Force enhancement for pure stretch conditions was ~20%, SSC_0s and SSC_0.5s produced significantly less FE (~10%) compared to the FE for the pure stretch condition. When a 1s interval (SSC_1s) was introduced between shortening and stretch, the effects of shortening on FE were abolished and the forces between the two conditions were similar. * Compared to FE (p<0.005).

Conclusion: From the results of this study, we conclude that active shortening preceding an eccentric muscle contraction affects the subsequent force enhancement, but only if the shortening and stretch follow each other within a sufficiently short time (less than 1s). Immediately after active shortening, the proportion of attached cross-bridges is reduced, but this reduced cross-bridge state is abolished with time. It appears therefore that the stretch-induced force enhancement is affected by the proportion of attached cross-bridges at the beginning of the stretch, and that this proportion is smallest when stretching immediately follows shortening, but is restored to its full capacity within about 1s of shortening. The molecular details of this observation need to be identified using a reduced (single fibre or myofibrillar) preparation.

EFFECT OF WHOLE BODY VIBRATION ON ISOKINETIC PERFORMANCE OF THE QUADRICEPS FEMORIS

Daniel T. Borges [1,*] Liane Macedo [1] Caio Lins [1] Jamilson Brasileiro [1]

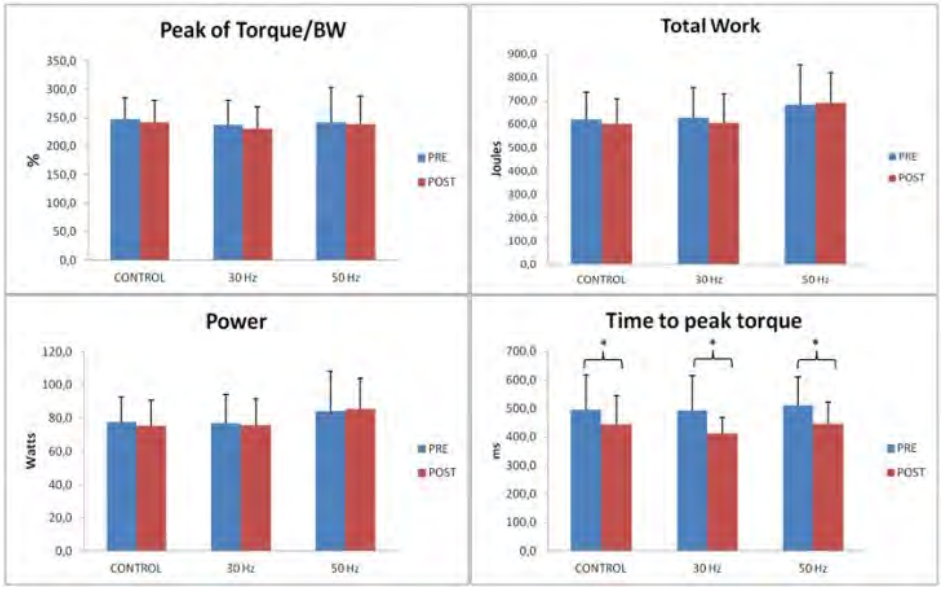
[1]Department of Physotherapy, Federal University of Rio Grande do Norte, Natal, Brazil

Introduction and Objectives: Whole body vibration (WBV) has become a popular practice in training and rehabilitation centers[1]. These are devices that produce vibrations in a wide range of frequencies and amplitudes that are transmitted in the form of mechanical energy to the body in order to create instability[2]. The mechanism by which the vibrating platform acts on body is based on the excitatory neuromuscular response. The vibratory stimulus acts on myotendinous structures, causing changes in the length of the fibers inducing excitation of the muscle spindles. Finally, the Ia afferent neurons facilitate the activation of alpha motor neurons causing a reflex muscle contraction[3].Although this is a widely used resource, there is a lack of consensus in the literature regarding the protocols to be applied, and the real benefits and immediate physiological responses triggered by vibration. Therefore, the present study aims to analyze the acute effects of an exercise protocol with WBV, in different frequencies, on the isokinetic performance of the quadriceps in healthy women.

Methods: This is a randomized controlled trial where 60 healthy and active women were randomly divided into three groups with 20 members each: control group (CG)-performed an exercise protocol without WBV; group 30 Hz - performed the exercise protocol with WBV, with frequency set at 30Hz and 4mm of amplitude, and 50 Hz group - performed the same WBV protocol at a frequency of 50 Hz and 4mm of amplitude. Initially volunteers performed a warm-up exercise on a stationary bicycle (5 min; 15 W; 20 km/h). Performance measurements were started 3 min after the warm-up. For isokinetic evaluation, volunteers were positioned on the dynamometer, stabilized by braces and with the device axis aligned with the evaluated knee. The machine's lever arm was attached to the distal region of the non-dominant leg. They were instructed to perform 5 maximal contractions only for knee extension at 60°/s, starting from 90° flexion up to full extension. Variables analyzed were peak torque normalized by body weight (PT/BW), total work, power and time of peak torque (TPT). Immediately after the isokinetic evaluation, intervention protocols were carried out. The 30 and 50 Hz groups performed an exercise protocol on the vibration platform, which was composed of an unilateral isometric semi-squat with the knee held in 40º[4], both arms extended at shoulder height and the trunk in upright position. Participants performed a total of 10 sets of 30s, with rest intervals of 30 s between sets[4, 5]. The knee angle was monitored with a universal goniometer to ensure that there were no changes in the amplitude during the protocol. The platform was turned on at the beginning of each series, established with a vibration frequency of 30 Hz or 50 Hz (depending on the group) and an amplitude of 4mm[6]. Volunteers of the CG group performed the exercise with the platform turned off and familiarization was allowed for all participants. After the application of the exercise protocols in the respective groups, all volunteers underwent a reassessment identical to the evaluation performed at baseline. Software SPSS (20.0) was used for statistical analysis. A One-way ANOVA was used to investigate baseline differences between groups. A Two-way repeated measures ANOVA was calculated to identify differences within and between pre- and post-tests. In the case of significance, post hoc comparisons (Bonferroni) were calculated additionally. A significance level of 5% was chosen.

Results: No significant differences in anthropometric measures or variables analysed were observed on the baseline evaluation between the groups. There was no significant difference in the values of PT/BW, total work and power regardless of the adopted frequency. There was a significant reduction in the values of TPT on the CG, 30Hz e 50Hz groups (P=0,18;P<0,001;P=0,003 respectively), but with no significant differences between them (Figure 1).

Figure:



Caption: Figure 1 - Means and standard deviation of peak torque normalized by body weight (PT / BW x 100), total work, average power and time to peak torque, pre and post implementation of the protocol on three groups: control, 30 Hz and 50 Hz.

Conclusion: The results of this study suggest that the exercise protocol associated with WBV is not able to significantly improve the isokinetic performance of the non-dominant quadriceps femoris of healthy and active women.

PO-0289

A PREDICTIVE EQUATION FOR ESTIMATING THE CONTRIBUTION OF BIARTICULAR MUSCLES TO PASSIVE JOINT MOMENT

Mark Hines [1 2,*] Neale Tillin [2] Raymond Lee [1]

[1]School of Applied Sciences, London South Bank University, [2]Life Sciences, University of Roehampton, London, United Kingdom

Introduction and Objectives: Hip joint moments during dynamic tasks are commonly modelled using the inverse dynamics method, based upon the Newton-Euler equations. In the inverse dynamics approach, the hip joint is considered to behave as a frictionless line-hinge (Koopman *et al.*, 1995), without appreciable interaction of passive structures. However, investigators have reported that passive structures about the hip joint can contribute considerably to the net moments measured during dynamic tasks, such as gait (Yoon and Mansour, 1982, Silder *et al.*, 2008, Whittington *et al.*, 2008).

The purpose of the present paper is to demonstrate the contribution of the posterior hip tissues to hip moments during passive flexion, and to develop an equation for the prediction of passive hip moments during active tasks, at various hip and knee angles.

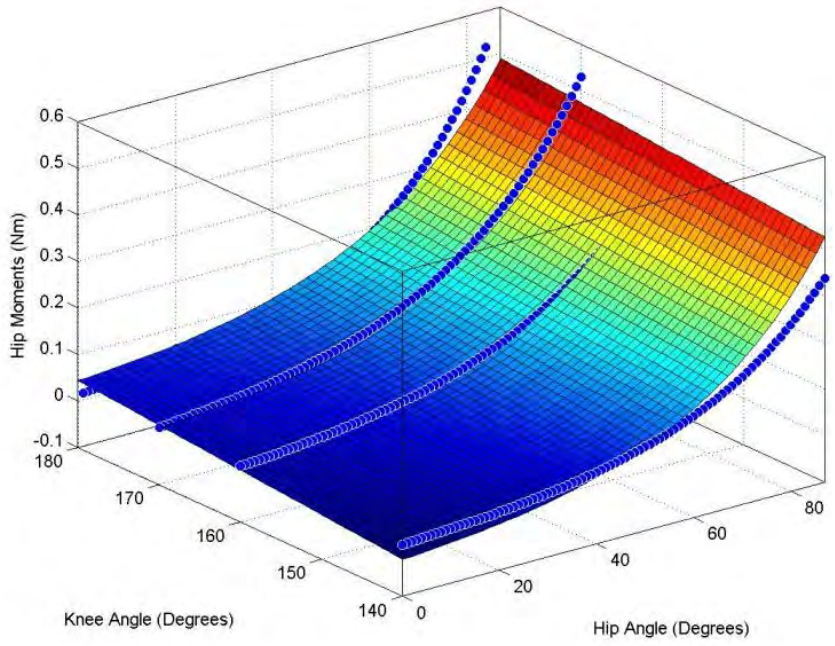
Methods: Hip moment-angle data from 52 subjects, measured during supine passive leg raising tests, was reassessed for development of the predictive equation. In the initial investigation, the knee had been supported in each of 4 angles from 180 (leg straight) to 140 degrees. Passive hip moments were measured using a custom-built force transducer.

To establish a predictive equation for passive moments, based upon a combination of hip and knee angles, plots were generated for assessing the changes in hip moments with hip angle, and at different knee angles independently. In agreement with other researchers, passive hip moments were found to increase exponentially as a function of hip angle. By introducing a variable knee angle component, it was found that this contributed a linear component to the model. A surface fitting programme was written for Matlab, and visual and residual analyses used to determine the most appropriate equation for the individual datasets.

Results: For both absolute and bodyweight-normalised moments, the mean adjusted r-squared was 0.894 (0.077), with a range of 0.603 to 0.995. For absolute moments, the mean RMSE was 2.059 (0.891), with a range of 0.588 to 4.8. For bodyweight-normalised moments, the RMSE was 0.029 (0.013), with a range of 0.007 to 0.062.

Figure 1 shows a surface plot of the ensemble mean of 3 passive moment curves at each of 4 knee angles, for a typical test participant. Table 1 shows the average, standard deviation and ranges for the equation coefficients. The coefficients interact for a given participant and therefore mean values should not be used to estimate passive moments.

Figure:



Conclusion: Models of dynamic movements that do not include a measure of passive contributions are at risk of overlooking an important biomechanical component. The following equation should be used to derive the contribution of passive moments about the hip during flexion, in dynamic movements utilising a variety of hip and knee angles

M(Passive) = a*theta(knee)+b*exp(c*theta(hip))+d

Table:

	Equation Coefficients			
	a	***b***	***c***	***d***
Mean	0.002	0.068	0.022	-0.307
Median	0.002	0.067	0.021	-0.302

WEBINARS SERIES AND INTERNET BROADCAST: A STRATEGY TO PROVIDED EDC REGIONS WITH ACCESS TO BIOMECHANICS

Emmanuel S. Da Rocha [1 2,*] Marco Vaz [2 3] Felipe Carpes [1 2]

[1]Applied Neuromechanics Group, Federal University of Pampa, Uruguaiana, [2]Brazilian Society of Biomechanics, [3]Biomechanics and Kinesiology Research Group, Federal University of Rio Grande do Su, Porto Alegre, Brazil

Introduction and Objectives: Access to education is still one of the main challenges in economically developing countries (EDC). In Academia, it is very common to hear from EDC members about their difficulties to travel abroad to attend international scientific conferences that gather scientist of the field. In the other hand, Internet access has significantly increased in EDC regions in the last years. The use of Internet for science divulgation is not a novelty, but in the field of Biomechanics there are very few online courses and materials available.

The purpose of this study was to show how internet-based tools are being used to divulgate Biomechanics, how the distance between the scientists and the academic apprentices in EDC can be decreased and what is the participants' perception on the themes presented by invited speakers and the importance of these themes for their academic lives.

Methods: Internet tools were used since 2011 to divulgate Biomechanics through online broadcasting tools provided by the Federal University of Pampa and the Federal University of Rio Grande do Sul, both Brazilian Universities. Using these tools, lectures were recorded and broadcasted online, and the records were later made freely available online worldwide. The recordings were made from webinars and lectures given by invited speakers, in Portuguese, English or Spanish. These activities were related to:

Monthly webinars

The monthly webinar involved lectures on topics of exercise and rehabilitation that were live broadcasted through the Internet. Upon speaker's agreement, lectures were recorded. This activity was developed since 2011 and is currently listed as an EDC project at the ISB webpage (isbweb.org/component/content/article/127-edc-projects/434-unipampa-brazil). Every January, an annual agenda of the invited lectures topics is made available on the Internet (porteiras.s.unipampa.edu.br/gnap/webinar). To watch the lecture online people interested should visit a specific URL (webconf.unipampa.edu.br/gnap). There is no need for previous registration and there is no fee to be paid. The University supports the webinar system. To watch recorded lectures the visitant needs to open the link (porteiras.s.unipampa.edu.br/gnap/webinar) and wait until the system loads the class. At the end of each live webinar people are requested to answer some questions concerning the experience online. Part of these answers are summarized in Figure 1. There was a positive feedback for all questions regarding the webinar.

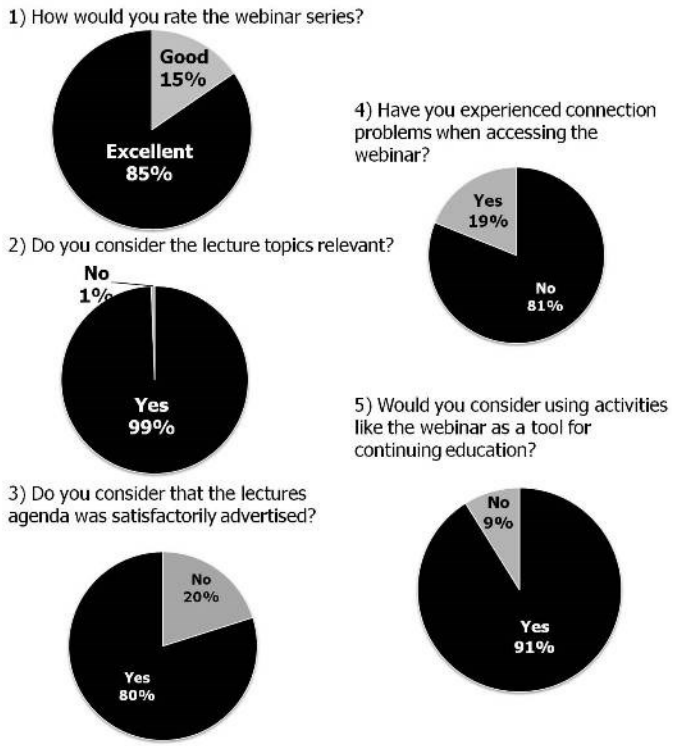
Online broadcast

Using the same method used for the webinars, live broadcast was used for MSc and PhD defenses and for other scientific events. One of the relevant examples that made scientific knowledge accessible worldwide was the broadcasting of the V Annual Symposium on Applied Neuromechanics, in October 23rd-25th 2014, where all lectures were live broadcasted and recorded for subsequent display. A special website was created where any person can access the lectures and watch

them online. The website link (sites.google.com/site/symposiumneuromechanics/neuromech-tv) does not require any login or registration.

Results: The webinar series consists of 36 online lectures in different topics since 2011. The average number of participants in each lecture ranged from 20 to 35, with some lectures bringing more attention than others. For example, a lecture on scientific writing had 45 participants and the lecture with the highest number of participants had 56 people online the same time. If we look at the total number of participants, in the last three years more than 700 logins were made on the webinar online system. Most of the participants attending the online lectures were from Brazil and South America, especially when the lecture was in Portuguese or Spanish. When lectures were in English, we observed a higher number of participants from other continents. Finally, a continuous interest was observed for accessing former lectures recorded, which also happens due to the different time zones. In Figure 1 a summary of the feedback received is shown.

Figure:



Caption: Figure 1. Feedback received from the participants.

Conclusion: The use of Internet to spread the knowledge in the field of Biomechanics is an efficient strategy to provide people from different places with access to information. Online lectures bring attention of a significant number of people, but it is still lower than the number of people we want to reach. Different time zones and the language barriers are some of the challenges to overcome when promoting strategies to increase access to online education in EDC.

PO-0291

EXPLORING THE CONSISTENCY OF MUSCLE CO-ACTIVATION ACROSS ACTIVITIES OF DAILY LIVING IN INDIVIDUALS WITH KNEE OSTEOARTHRITIS

Stephanie L. Smith [1,*] James Woodburn [1] Martijn Steultjens [1]

[1]School of Health and Life Sciences, Glasgow Caledonian University, Glasgow, United Kingdom

Introduction and Objectives: Individuals with knee osteoarthritis (KOA) exhibit different movement and muscle activation patterns compared to matched controls. These changes in muscle activation can be seen in muscle co-activation levels, whereby individuals with KOA demonstrate high levels of muscle co-activation compared to controls. High co-activations levels are thought to be neuromuscular adaptations to promote dynamic joint stabilisation; however, it is also thought that high muscle co-activation increases joint load and may therefore be detrimental to the progression of KOA. The purpose of this study was to explore the consistency of muscle co-activation across different activities and explore specific areas of co-activation during different phases of walking.

Methods: Neuromuscular performance of 25 symptomatic KOA (60.9 ± 9.5 yrs; 30.4 ±5.9 kg/m^2) participants and 4 controls (50.8 ± 2.0 yrs; 25.8 ±4.8 kg/m^2) was assessed using electromyography (EMG) and ground reaction forces recorded during a series of walking, stair ascent and descent and sit to walk trials at self-selected speed. Gait was split into phases (pre loading, loading response, early, mid and late stance). EMG was recorded from 7 sites (medial/lateral gastrocnemius, biceps femoris, semitendinosus, vastus lateralis/medialis and rectus femoris). All trials where normalised to maximal voluntary isometric force contractions (MVC). Peak force and muscle co-activation index (CI) were calculated from the normalised EMG for all activities using the following equation CI = (lowerEMGi/higherEMGi)*(lowerEMGi+higherEMGi) where lowerEMGi is the antagonist (least active muscle) and higherEMGi is the agonist (most active muscle) [1,2]. Pearson's correlations where performed to assess the relationship between muscle co-activation across different activities.

Results: Table 1 shows the CI for hamstring-quadriceps (H:Q) co-activation across different activities for both the KOA and control group. CI's were higher in the KOA group than among controls. Within the KOA group, correlation for the H:Q CI between activities was r = 0.558. Similar patterns were observed for the other muscle combinations (range of correlation r = -0.140 to -0.602). There was a strong negative correlation between MVC and CI in the KOA group. When comparing CI's within one activity for different muscle combinations, again a moderate positive correlation was observed between the CI's r = 0.372. High CI's (r = -0.660 - -0.628) were found for medial-lateral co-contraction within the same muscle group (i.e., between vastus medialis and lateralis, semitendinosus and biceps femoris respectively).

Conclusion: Participants with KOA demonstrated high muscle co-activation compared to controls. When muscle co-activation was correlated between activities it demonstrated that individuals with high muscle co-activation remained high across all activities. When looking at muscle combinations participants with KOA high muscle co-activation was most prevalent in the H:Q and medial - lateral muscle groups and most pronounced in the vastus lateralis – vastus medialis muscle co-activation. Although it remains unclear whether high muscle co-activation may be detrimental or beneficial to

KOA disease progression, high muscle co-activation may indicate loss of neuromuscular control in participants with knee osteoarthritis.

Table:

	KOA	Control
Stair dscent	-0.629	0.584
Stair descent	-0.675	0.308
Sit to walk	-0.660	0.863
Gait (stance)	-0.376	-0.624
Pre loading	-0.605	0.295
Loading response	-0.623	0.548
Early stance	-0.490	0.520
Mid stance	-0.620	0.638
Late stance	-0.564	0.511

PO-0292

SHORTENING-INDUCED FORCE DEPRESSION IN HUMAN ADDUCTOR POLLICIS DURING FATIGUE

Ian C. Smith [1,*] Geoffrey A. Power [1] Rafael Fortuna [1] Walter Herzog [1]

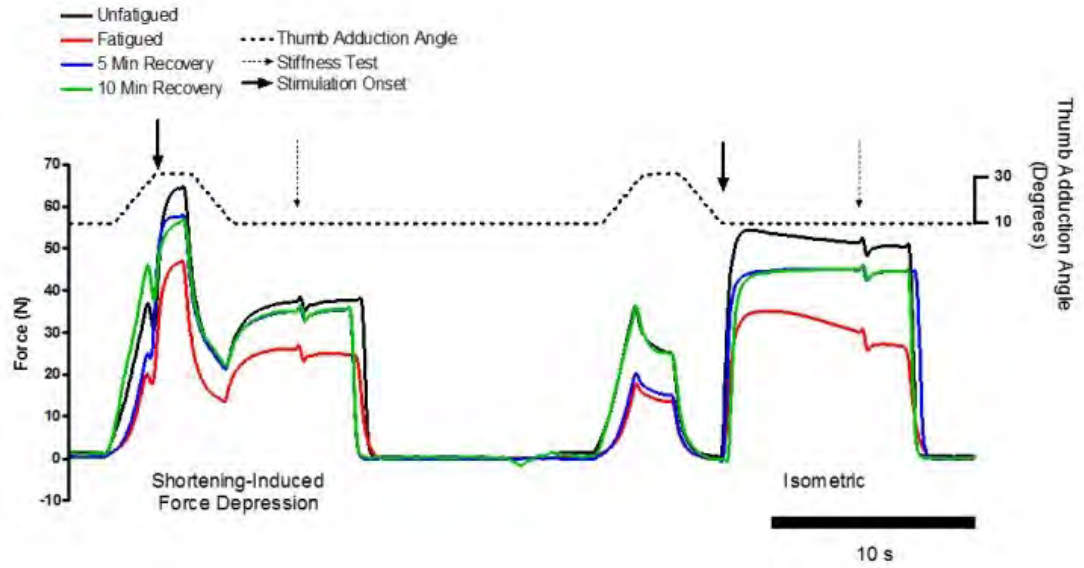
[1]Human Performance Laboratory, University of Calgary, Calgary AB, Canada

Introduction and Objectives: Muscle force production is highly history-dependent. For example, a muscle which has undergone active shortening produces less force than a purely isometric contraction at the same final muscle length and activation level. This intrinsic property of muscle, known as shortening-induced force depression (FD), is thought to result from stress-induced changes to the actin filaments inhibiting cross-bridge formation. However, the precise nature of these changes is not well understood. The torsional and flexural rigidity of the actin filament is known to be affected by the specific entity occupying the specific metal cation (K^+, Mg^{2+}, Ca^{2+}) and nucleotide (ADP, ATP) binding sites located on actin, with greater flexibility when Mg^{2+} and ADP are bound [1]. It is possible that the higher Mg^{2+} and ADP concentrations associated with muscle fatigue could affect the entities present at these sites, imparting greater susceptibility of stress-induced deformations to the actin filament, and increase the amount of shortening-induced FD. Thus, the present study was aimed at determining if shortening-induced FD is affected by fatigue during electrically-evoked contractions in the human adductor pollicis muscle.

Methods: Contractions were electrically induced in the adductor pollicis of healthy young participants via Ag-AgCl electrodes placed over the ulnar nerve. Stimulation was applied at 50 Hz with current sufficient to elicit 50-60% of maximal voluntary force. Shortening-induced FD was measured by passively stretching the thumb to a 30° adduction angle prior to the onset of stimulation, and then actively shortening the muscle at a rate of 20° s^{-1} to 10°, with total contraction duration of 4 s. Purely isometric contractions were performed at a thumb adduction angle of 10° for 4 s and served as a reference. In the unfatigued state, the shortening-induced FD and pure isometric measurements were performed 3 minutes apart. Fatigue was then induced by occluding blood flow to the arm via a pressure cuff, and then applying constant 50 Hz stimulation until force was reduced to 40% of the initial value. Prior to cuff deflation, shortening-induced FD was measured and compared to the average results of isometric contractions applied before and after the shortening contraction. The transient nature of fatigue made it necessary to test the shortening and isometric contractions in rapid succession (~10 s apart). Recovery of FD was similarly monitored at 5 and 10 minutes following cuff deflation. Stiffness of the adductor pollicis was measured using a rapid 2° increase in adduction angle (500° s^{-1}). Sample recordings are shown in Figure 1.

Results: The fatigue intervention resulted in a 31±2% decrease in force and a 27±4% reduction in stiffness during the isometric reference contractions ($P<0.05$). Similarly, work performed during the 20° shortening contraction was 27% lower in the fatigued state ($P<0.05$). While the absolute magnitude of shortening-induced FD was lower in the fatigued state than the unfatigued state, the relative level of FD was not different between conditions (Table 1). Despite the force differences, no differences in muscle stiffness were detected between the purely isometric and force depressed state. Ten minutes following cuff release, isometric force and stiffness had returned to 88±1% ($P<0.05$) and 90±4% (not significant), respectively of the values seen in the unfatigued state.

Figure:



Caption: Figure 1: Sample tracings from human adductor pollicis angle displacement (top) and force production (bottom) for the different conditions tested. Isometric and shortening contractions were performed 3 minutes apart in the unfatigued state. All other conditions were performed approximately as shown with minor temporal shifts (<5 s) to synchronize the records.

Conclusion: The reduced absolute magnitude of shortening-induced force depression during fatigue is consistent with the well documented effects associated with lower stress during shortening, and shortening-induced FD does not appear to be otherwise modified by fatigue. Future work should focus on examining the structure of the actin filament during shortening contractions.

Table:

Condition	50 Hz Force (N)	Work Performed During Shortening (mJ)	Force Following Shortening (N)	Force Depression (N)	Force Depression (% 50 Hz Force)
Unfatigued	55.2 ± 1.4	80 ± 3	37.9 ± 0.5	17.3 ± 1.0	31.2 ± 1.1
Fatigued	38.0 ± 0.8 *	58 ± 6 *	29.9 ± 2.8 *	8.2 ± 2.6 *	21.4 ± 6.7
5 min Recovery	50.7 ± 2.3 †	81 ± 12 †	39.3 ± 4.9 †	11.4 ± 2.8	22.6 ± 6.3
10 min Recovery	48.7 ± 1.8 * †	82 ± 9 †	37.3 ± 4.2 †	11.4 ± 2.6	23.6 ± 5.9

FINGERTIP FLEXION FORCE AND MINIMIZATION OF THE SECONDARY MOMENTS AFTER TENDON TRANSFERS FOR RADIAL NERVE PALSY.

Florent PACLET [1,*] François MOUTET [2] Franck QUAINE [3]

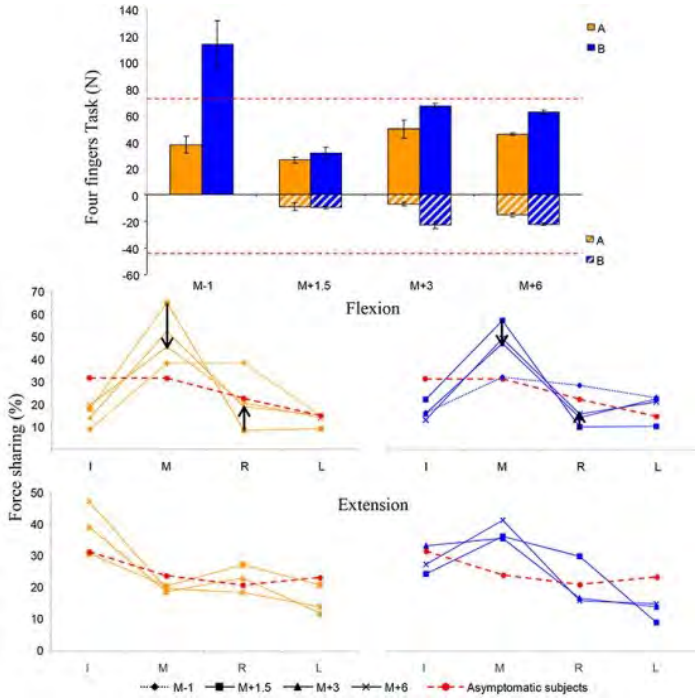
[1]INCIA, Bordeaux University, Bordeaux, [2]Unit of Hand Surgery, Grenoble CHU, [3]GIPSA-Lab, Grenoble University, Grenoble, France

Introduction and Objectives: High radial nerve palsy induces the loss of extension in the thumb, fingers and wrist. Tendon transfer surgery uses remained active flexor muscles to restore these lost functions by rerouting the tendon paths. The aim of this study was to investigate how the fingertip forces change following a tendon transfer surgery when performing a finger pressing task. In this study, the transfer procedure corresponds to the Tsugé technique. The principle of minimization of the secondary moments is described as a simple rule to understand the hand biomechanics [1]. It's used by the CNS to solve musculoskeletal redundancy: during the application of four-finger task, a stable force sharing among fingers is adopted to minimize unnecessary rotational moments of the hand. Since High radial nerve palsy and tendon transfer surgery modify the number of muscles crossing the finger and wrist joints, our objective was (i) to characterize the flexion and extension resultant force changes following the transfer, and (ii) to determine if the principle of minimization of the secondary moments of the hand remains valid after tendon transfers for flexion and extension forces.

Methods: 19 asymptomatic subjects and two patients (A and B) with high radial nerve palsy performed four-finger pressing task (i.e. I M R L for Index, Middle, Ring and Little fingers) with the distal phalanx (P3) and four-finger extension task with the proximal phalanx (P1) at maximal intensity. Patients were followed before (M-1) and after (from M+1.5 to M+6) the surgery for a total of 6 months. 4 Kistler force sensors were used to record vertical forces applied by each fingertip in flexion and extension with fingers in a neutral posture. Resultant force in flexion and extension corresponds to algebraic sum of each fingertip force.

Results: Fig. 1 (Top) illustrates fingertip force patients applied in flexion and extension during the follow-up. Results showed both patients have recovered the extension force after the surgery, with an increase during the follow-up (force doubles in 6 month). This force was always inferior to the one observed in asymptomatic subjects. Flexion force reduces just following the surgery, and then increases until three month after the surgery. From three to six month, no significant change was observed in both patients. One can note the force applied by patient B was superior to the asymptomatic subjects force before the surgery (red line), and almost equal after the surgery. The principle of minimization of the secondary moments is presented in Fig.1. Flexion force value (Middle) for each finger changes after the surgery, but it tends to go back to the flexion force sharing pattern computed before the surgery. This pattern is very similar to the one computed for asymptomatic subjects (red dotted line). Concerning extension (Bottom), we observed force distribution is different for each patient with no obvious stable sharing.

Figure:



Caption: Fig 1: (Top) Fingertip force 1 month before the surgery (M-1), and after the surgery (M+x) for patient A and B. (Middle) Force sharing pattern for flexion force in both patients (A left, and B right). The black arrow indicates the tendency during the recovery phase. (Bottom) Force sharing pattern for extension force in both patients (A left, and B right). For each graph, red line represents the results for asymptomatic subjects

Conclusion: We observed extension force recovery after the surgery. For one patient (B) this force equals half the force of the asymptomatic group. In the same time, the flexion force drastically reduces just after the surgery, but in spite of the reduction of the number of flexor muscles involved in the task (donor muscles), the force increases in a second time. This force may be still improved since it is superior to the one applied before the surgery. This result confirms the rule in tendon transfer surgery meaning that the procedure used for the transfer does not deteriorate the force production in flexion. For flexion force, force sharing pattern across finger is changed after the transfer, but tendency seems to be the comeback to the initial value during recovery period. We can thus conclude rerouting several flexor muscles for tendon transfers for radial nerve palsy does not modify the way the subject shares the force at the fingertips in flexion. In extension, comparison is more hazardous since this pattern doesn't dependent on the subject motor strategy. In fact, only one muscle is grafted on the finger extensor tendons and theoretically the force sharing pattern should be fixed by the initial tensioning and should remain stable without any possible change. We conclude the principle of minimization of the secondary moments may apply in flexion for hand biomechanics after tendon transfer. It may thus be considered as a simple tool to characterize restored hand biomechanics after tendon transfers.

BEHAVIOUR OF HUMAN GASTROCNEMIUS MEDIALIS MUSCLE ARCHITECTURE FOLLOWING MAXIMAL ISOMETRIC FATIGUING CONTRACTIONS

Neil M. Thomas [1,*] Susan Dewhurst [1] Theodoros Bampouras [1]

[1]Department of Medical and Sports Sciences, University of Cumbria, Lancaster, United Kingdom

Introduction and Objectives: By combining ultrasound measures of muscle fascicle length changes with estimations of muscle-tendon unit (MTU) length, researchers have been able to examine the interactions between the contractile and elastic components of MTUs [1]. This method, however, assumes fascicles imaged in a specific region of a muscle exhibit the same magnitude of shortening as fascicles throughout the muscle. Although uniform fascicle behaviour has been demonstrated in the non-fatigued human *gastrocnemius medialis* (GM) [2], widely studied in the literature, there has been no consideration of the potential modification of fascicle homogeneity following fatigue. This raises important questions for the accuracy of GM MTU modelling implemented under the assumption of homogenous fascicle behaviour, in fatigued conditions. The aim of the present study, therefore, was to assess the effects of fatigue on human GM fascicle behaviour.

Methods: With Institutional ethical approval, fifteen male participants (age 21.9 ± 4.1 years, mass 84.0 ± 13.6 kg) performed repeated isometric plantar flexion maximal voluntary contraction (MVC) until peak force fell 30% below an initial baseline MVC. Force from the isometric contraction was measured with a force gauge (Myometer, MecMesin, West Sussex, UK), with the ankle joint at 90°. B-mode ultrasonography (Voluson-i, GE Medical Systems, Zipf, Austria) was used to measure GM muscle fascicle length and pennation angle at distal, middle, and proximal regions at rest and during MVC prior to and following the fatiguing contractions. The middle region of the muscle was defined as the middle of the mediolateral width, at the point with maximal anatomical cross-sectional area, with distal and proximal regions 35mm longitudinally from this point [2]. The effects of muscle region and fatigue state on fascicle length and pennation angle at rest and during MVC were assessed using a 2x3 RM ANOVA protocol. Bonferroni corrected pairwise comparisons were used where applicable.

Results: There was a significant increase in fascicle length during MVC in the distal (2.8mm, 8.1%, $p<0.05$) middle, (4.9mm, 14.1%, $p<0.05$), and proximal (5.2mm, 14.7%, $p<0.05$) regions post-fatigue compared to pre-fatigue. There was also a significant reduction of pennation angle during MVC in the distal (3.3°, 8.8%, $p<0.05$), middle (3.9°, 9.4%, $p<0.05$), and proximal (2.9°, 6.9%, $p<0.05$) regions post-fatigue compared to pre-fatigue. These changes, however, were not region specific. There were no alterations of GM architecture at rest post-fatigue compared to pre-fatigue.

Conclusion: Repeated fatiguing contractions caused a significant reduction of fascicle shortening during isometric MVC, and this reduction was uniform at all regions of interest. The maintained fascicle shortening uniformity following fatigue supports the assumptions of biomechanical models of muscle-tendon interaction in fatigued conditions. The reduction of fascicle shortening indicates that fatigue induced a change in the behaviour of the fascicles which, owing to previous literature [3], may reflect the effects of some of the peripheral mechanisms of muscular fatigue.

BIOMECHANICS OF CHILDBIRTH AND UPRIGHT POSITIONING DURING LABOUR: GLOBAL HEALTH IMPLICATIONS

Andrea Hemmerich [1,*] Geneviève Dumas [2] Rajani Mullerpatan [3]

[1]Economically Developing Countries (EDC) Programme, International Society of Biomechanics, Ottawa, [2]Dept. of Mechanical and Materials Engineering, Queen's University, Kingston, Canada, [3]School of Physiotherapy, MGM Institute of Health Sciences, Navi Mumbai, India

Introduction and Objectives: Positions of labour are often culturally dependent. In non-Western settings including most developing countries, upright postures such as squatting or kneeling are often naturally adopted. Despite recommendations from the World Health Organization against routine use of a supine position during childbirth, this is still the most common delivery position of women in heath centres, which may be attributed to caregiver preference and Western ideals rather than comfort of the mother.

Upright birthing positions are associated with several benefits such as greater ease and positive perception of the mother, shorter labour, and fewer episiotomies and assisted deliveries [1]. Researchers have suggested numerous biomechanical distinctions associated with upright birthing positions, including stronger uterine contractions and gravity, improved alignment, and greater pelvic outlet area which increase the effectiveness of the passage of the fetus for a shorter labour [1,2]. Using non-medicalized approaches to improve birth outcome would be especially beneficial in developing countries where access to medical resources are often scarce. The biomechanical mechanisms of birth positioning that contribute to specific physiologic outcomes have yet to be adequately explored and understood, however.

The primary purpose of this research was, therefore, to conduct a review of birth complications originating from biomechanical difficulties that could potentially be addressed by mobility and change in birth position during labour and delivery. The secondary objective was to compare incidence of these birth complications in developed and developing countries and the underlying reasons (related to risk factors) for observed differences.

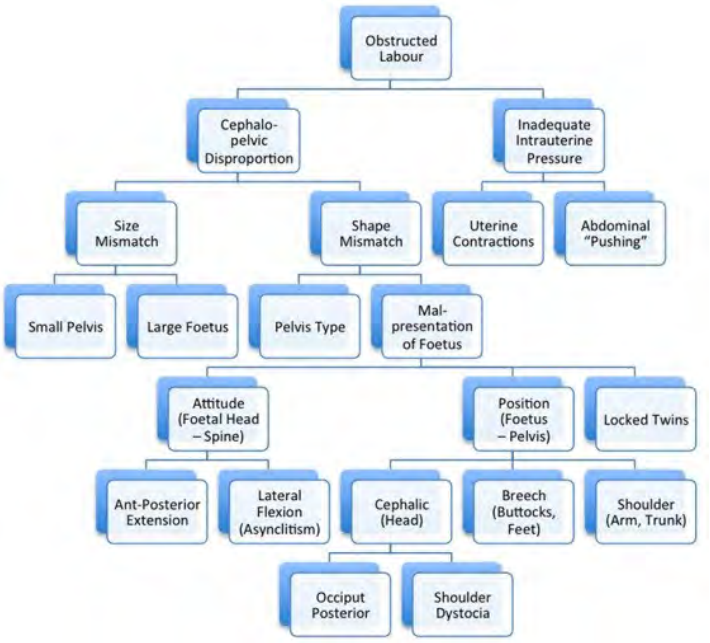
Methods: Scientific and clinical knowledge on the mechanics of the second stage of labour and associated complications in various populations was synthesized to explore potential links between maternal positioning and birth outcome. A review of available data in the fields of biomechanics, clinical medicine, epidemiology, and anthropology was conducted. Due to the lack of rigorous, scientific publications on related material, in particular in developing countries, additional resources were examined, including guidelines and reports produced by global health institutions, informal online literature, and interviews with experts.

Results: The primary biomechanical complication of childbirth is obstructed labour, in which the maternal propulsive power is inadequate to overcome forces opposing delivery, resulting in the inability of the foetus to pass through the birth canal. Resistance is most often due to cephalopelvic disproportion (a geometric mismatch in pelvis and presenting part of the foetus), which may be caused by several maternal and/or foetal irregularities (Figure 1).

Obstructed labour may result in serious consequences and even death if untreated. Trauma in the form of tearing or stretching of the perineum, bladder, or rectum can cause vaginal or uterine prolapse or incontinence in the longterm. If

neglected for too long, obstructed labour could result in impaction of the presenting part of the foetus causing pressure necrosis leading to obstetric fistula. A ruptured uterus may result in haemorrhage, shock, and maternal death.
Poor outcomes in the newborn include fractures of the clavicle, brachial nerve damage, and in severe cases hypoxia leading to brain damage or death.
The prevalence of these outcomes is typically greater in developing countries due to both a lack of skilled birth attendants and/or sterile instruments that could facilitate delivery (e.g. Caesarean section) or repair the trauma that may ensue. In addition, several risk factors are more prominent in developing countries, such as malnutrition and early age of pregnancy, which may both account for smaller maternal pelvic dimensions [3].

Figure:



Caption: A biomechanical frame of reference for major complications of childbirth.

Conclusion: In this study we have highlighted an area of women's health that could greatly benefit from further biomechanical research in order to positively influence clinical practice. Although mobility and changing position during labour and delivery has potential to improve maternal and neonatal birth outcome while concomitantly demedicalizing perinatal care, many care providers are reluctant to change practice due to insufficient evidence and insight into the link between dynamic musculoskeletal mechanics and clinical outcome. Implications of childbirth biomechanics research, specifically on maternal positioning, may be greater in developing countries due to associated risk factors and lack of available resources for treatment.

KNEE JOINT STRUCTURE FORCES IN INCLINED WALKING AT SELF-SELECTED AND PRE-SET SPEED

Hermann Schwameder [1,*] Nathalie Alexander [1]

[1] Sport Science and Kinesiology, University of Salzburg, Hallein, Austria

Introduction and Objectives: Uphill and downhill is associated with increased knee joint loading compared to level walking [1,2,3]. Inclined walking typically leads to reduced walking speed indicating a clear correlation with the amount of inclination. When investigating the effect of the magnitude of the inclination on joint loading parameters one approach is keeping the walking speed constant for all conditions in order to provide comparative conditions, however, this does not correspond with the typical speed adjustment on inclined surfaces. Another approach is to allow self-selected speed, but in this case the comparison between the inclination conditions is restricted. Thus, the purpose of this study was to compare knee joint structure forces in inclined walking at differently inclined surfaces while walking at a pre-set and self-selected speed. Furthermore, it was investigated if differences in knee joint loading regarding the two conditions can be explained by the differences in walking speed.

Methods: 18 healthy male participants (27.0 ± 4.7 y, 1.79 ± 0.05 m, 74.5 ± 8.2 kg) were recruited for this study. The participants were asked to walk on a ramp (6 m x 1.2 m) with two integrated force plates (AMTI, USA, 1000 Hz) at different inclination angles of -18°, -12°, -6°, 0°, 6°, 12° and 18°. They had to perform three valid trials both with a constant pre-set speed of 1.11 m/s and a self-selected walking speed. In the pre-set condition the trial with the speed closest to the aimed speed and in the self-selected condition the median trial were used for further analysis. Kinematic data were captured with a twelve-camera, marker based motion capture system (Vicon, UK, 250 Hz). The knee structure forces were calculated using a 2D, quasi-static knee model [2] and were normalized to body weight (BW). ANOVA with repeated measures were used to check for statistical significance. The magnitude of the walking speed effect on the differences was determined using correlation and ANCOVA approaches.

Results: Table 1 shows the tibio-femoral contact force (Ft), the patella-femoral compression force (Fcp) and the quadriceps tension force (Fq) in the self-selected (-s) and pre-set (-p) conditions. As expected the knee structure forces in both conditions increase continuously and significantly with inclination, while the magnitude of increase is more pronounced in downhill (up to 6.9 BW) compared to uphill walking (up to 4.2 BW). The differences of the knee structure forces between the two conditions are rather small and do not exceed 0.51 BW. The largest deviations can be observed for the level walking conditions. Due to the low forces the relative differences in this condition reach magnitudes of about 25%, though. While the structure forces for the -18° and -12° inclinations are higher in the pre-set condition, the opposite relation has been observed for the remaining inclinations. The correlation and ANCOVA analyses showed that more than 80% of the differences between the two walking conditions can be explained by the differences in walking speed.

Conclusion: Walking with self-selected and pre-set speed leads to relatively low differences regarding the knee joint structure forces. To conclude, depending on the purpose of the study each of the walking speed approaches is applicable without causing pronounced changes of the structure forces in the knee. Due to the high correlation between the walking speed and the differences of knee structure forces a normalization of structure forces on walking speed is a reasonable measure to make diverse walking conditions better comparable.

Table:

inclination	Ft-s	Ft-p	Fcp-s	Fcp-p	Fq-s	Fq-p
-18°	5.48	5.91	5.63	5.96	6.50	6.94
-12°	5.16	5.17	4.96	5.09	5.99	6.09
-6°	3.34	3.07	2.94	2.65	3.94	3.66
0°	2.91	2.40	1.97	1.57	2.79	2.29
6°	3.43	3.23	2.22	1.97	2.69	2.42
12°	3.94	3.72	3.38	3.04	3.70	3.36
18°	3.93	3.92	4.06	3.95	4.21	4.12

EVALUATION SACROILIACA TEENS IN A PUBLIC SCHOOL OF THE SANTA MARIA, RS, BRAZIL

Estele C. W. Meereis [1,*] Sandra C. Morais [2] Mithielle A. Machado [3] Veronica J. Casarotto [4] Tatiele Zulian [3]

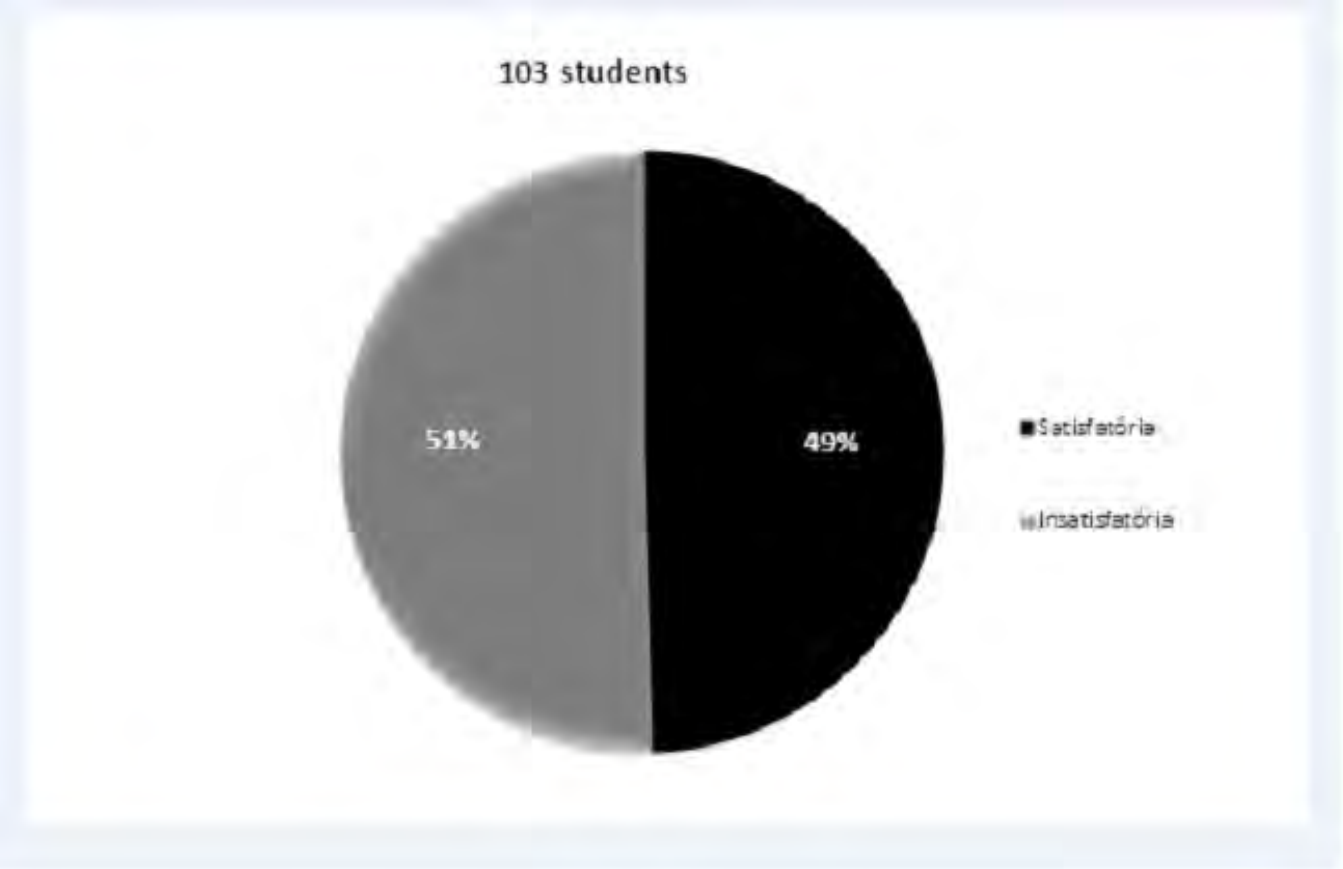
[1]Postgraduation in Human Movement Sciences, Federal University of Rio Grande do Sul, Porto Alegre, [2]1Graduation in Biological and Behavioral Aspects of Physical Education and Health, [3]Specialist, Federal University of Santa Maria, [4]Physiotherapist, Franciscan University, Santa Maria, Brazil

Introduction and Objectives: Obesity and overweight in adolescence are global public health issues (Catenacci, HILL, WYATT, 2009; ENES, SLATER, 2010) including Brazil. Thats factors such as musculoskeletal discomfort, general lack of mobility and poor lower limb alignment are more common in overweight children and collaborate to perpetuate the accumulation of fat (Taylor et al, 2006). Thus, this study aimed to verify the relation between central adiposity and mobility and structural problems in the iliac sacrum region in adolescents in the city of Santa Maria (RS).

Methods: This research is a cross-sectional descriptive study with High School students from a public school in Santa Maria, RS. For the analysis of body composition: portable digital scale, waist circumference, and hip circumference. The physical therapy evaluation was performed following the evaluation criteria for iliac using active physiological mobility test of bending forward and the iliac placement test. The intrapelvic movement was detected as follows: the teenager was made stand with his or her weight evenly distributed on both legs, while the physiotherapist removed with thumbs the excess of skin so the fingers could stay in the best position, with better sensitivity of bone process. Also, the physiotherapist fingered the underside of the posterior superior iliac spine (PSIS), on both sides. The teenager would bend the trunk forward so that the symmetry of the two PSIS could be observed. Both of them were to perform the same movement downward, therefore showing normal movement. Data were analyzed using simple descriptive statistics (average, standard deviation and percentage). In comparing the groups with presence or absence of hipomobility, we used the Student T test. For comparison between genders the chi-square test was performed. Statistically significant differences were considered when the P value was lower than 0.05. The software used was SPSS version 15.0.

Results: 103 adolescents were evaluated with an average age of 15.35 + 0.84 years, of which 53.4% (n = 55) were female. Of the total sample 74.7% (n = 62) were considered non-obese (eutrophic and thinness). In tests for mobility of the iliac, it was observed similarity in the number of adolescents (n = 103) who have demonstrated alignment and those who have demonstrated to have some changes, as described in Figure 1. These data are considered worrisome, since the iliac reflects not only bad posture from students, but also deficiencies that may be related to the movement. When comparing the anthropometric variables among adolescents (n = 103) with and without the changes in the iliac, it is observed that the students who had pelvic alignment in the active test had weight and waist and hip circumference statistically higher than those who did not show abnormalities. When the test result was the presence of left hipomobility (HE) there were no statistical differences in anthropometric variables between students with and without this alteration, except for the hip circumference (HC), in which those with this change showed higher HC, as shown in Table 1.

Figure:



Caption: Iliac positioning Assessment adolescents from a public school in Santa Maria-RS

Conclusion: Half the population had dysfunction in the iliac mobility, showing an unsatisfactory result. There was prevalence of changes in the iliac mobility tests with predominance of hipomobility to the right. We observed that the students who had pelvic alignment in the active test had weight and waist and hip circumference statistically higher than those who did not have any change

Table:

THE INFLUENCE OF RESIDUAL FORCE ENHANCEMENT ON MUSCLE OXYGENATION STATUS DURING SUBMAXIMAL VOLUNTARY CONTRACTION OF M. QUADRICEPS FEMORIS

Florian K. Paternoster [1,*] Wolfgang Seiberl [1] Daniel Hahn [2] Ansgar Schwirtz [1]

[1]Biomechanics in Sport, Technische Universität München, Munich, [2]Human Movement Science, Ruhr-University Bochum, Bochum, Germany

Introduction and Objectives: When an active muscle is stretched the resulting post-eccentric steady-state force at a given level of activation is known to be greater than the isometric force at the corresponding muscle length or for a given force less muscle activation is required at the same muscle length. Especially the characteristics of activation reduction of this so- called residual force enhancement (RFE) were associated with possible reduced metabolic costs compared to a pure isometric contraction. Recently, Joumaa and Herzog [1] could show a reduction in the ATPase activity per unit of force for the isometric contraction after active stretch, compared to the purely isometric contraction for a skinned fibers from rabbit psoas muscle. However, it is unclear if these findings of stretch-induced energetic savings can be transferred to human muscle function. Therefore, oxygen consumption of human quadriceps femoris was measured during and after submaximal voluntary lengthening and pure isometric reference contractions.

Methods: Unilateral submaximal isometric-eccentric-isometric (iso. -ecc. -iso.) and purely isometric knee extensions of n=10 subjects were measured using a motor-driven dynamometer (IsoMed 2000, D&R Ferstl, GmbH). The stretch amplitude was 20° (80°-100° knee flexion, 0° refers to full knee extension) and angular velocity was set to 60°s^{-1}. Muscle activation from mm. rectus femoris (RF), vastus medialis (VM) and vastus lateralis (VL) were measured using a sEMG system (OT Bioelecttronica, 4000Hz). For the calculation of the voluntary activation (VA) and the assessment of fatigue, the interpolated twitch technique was used. Muscle oxygenation status of m. VM and m. VL was measured by means of near infrared spectroscopy systems (PortaMon/PortaLite, artinis medical systems, 10 Hz).

First experimental session started with 3 MVCs, followed by a 60s fatiguing, isometric contraction at a submaximal torque level of 60% MVC, controlled via biofeedback software. Directly afterwards an additional MVC was performed to evaluate fatigue. The second session contained an iso.-ecc.-iso contraction, with an identical experimental protocol. Test sessions were separated by 4 hours to fully recover prior to the second session. If the differences between MVCs before sessions one and two exceeded 5%, subjects were excluded from the study.

Statistical analysis of baseline parameters contained MVC torques, VA level and resting twitches (RT). For the sustained contractions torque, muscle activation and oxygen consumption was analyzed during 6 time windows, one every 10 seconds after the onset of the contraction. The muscular oxygen consumption was defined by the maximum slope of the tissue saturation index. Data was tested for normality and repeated measures ANOVA with post-hoc comparisons were used for statistical analysis ($p<0.05$).

Results: There were no significant differences of baseline values before the sustained contractions of the first and second session. PT level ranged between 148Nm ± 38.36Nm and 147.50Nm ± 38.8 Nm, VA was between 96.49% ± 3.43% and 95.75% ± 4.22% and RT was 44.46Nm ± 20.12Nm for the first and 44.96Nm ± 20.68Nm for the last session. Also during

the 60s fatiguing contractions of first and second session there were no differences in muscle activation and oxygen consumption between purely isometric and lengthening contractions ($p > 0.05$). After the sustained contractions sessions one and two, there was a significant decrease in MVC torque and RT of about 30%.

Conclusion: The results are not in accordance with previously published findings. Seiberl et al. [2] found AR in the quadriceps femoris with an identical setup at the same submaximal MVC level. Although baseline values at the beginning of the two sessions did not reveal differences, the lack of RFE in our setup might still be due to the uncompleted recovery after the first session. VA and RT provides some information about central and peripheral fatigue, but as the complete mechanisms of RFE are still not understood, there might be other factors sensible to fatigue that are responsible for the absence of RFE in this study. Despite high torque level of 60% MVC in our setup, some subjects showed a reoxygenation of the VL and VM during the endurance contractions, which might has biased the relation of consumed oxygen in muscles. An increased time of recovery as well as the use of a mechanical cuff to create full occlusion of thigh muscle thereby suppressing reoxygenation is planned for future work in order to investigate possible energetic benefits of stretch-induced AR.

CAN PATELLA TENDON SLACK LENGTH BE MEASURED IN VIVO?

Taija Finni [1,*] Johanna Toivonen [1] Neil Cronin [1]

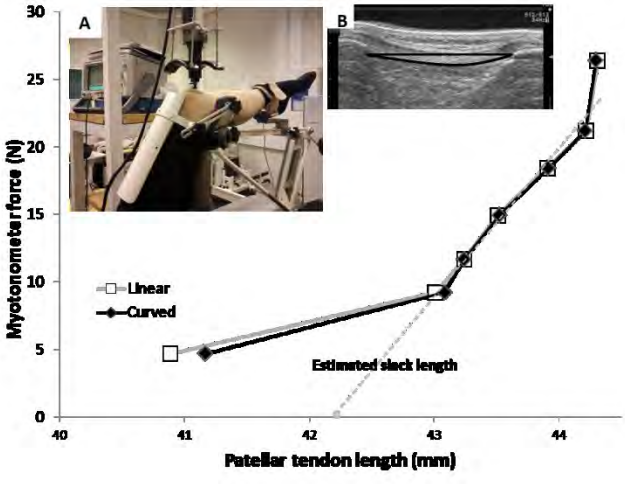
[1]Department of Biology of Physical Activity, University of Jyväskylä, University of Jyväskylä, Finland

Introduction and Objectives: Muscle-tendon slack length is an important parameter in muscle models but it is difficult to estimate in vivo. The muscle-tendon unit is at slack length when it does not exert any passive tension. Slack may be associated with curvature in some structures that can be visualized but force measurements are very difficult. This study assessed changes in patellar tendon length using curved and linear paths, while also measuring the tendon's resistance to compressive forces using a myotonometer. If initial tendon lengthening occurs without an increase in resistive force, this method could potentially be used to identify patellar tendon slack length.

Methods: Twelve physically active healthy female volunteers (age 23.3 ± 2.8 years, height 165.9 ± 5.4 cm and mass 61.3 ± 6.2 kg) lay supine on a custom-made table with the knee joint at 120° (Fig.1A). Patellar tendon length was measured using ultrasonography (both linear and curvilinear paths were assessed, within-analyser reliability >0.965, Fig 1B), and tendon force response to perpendicular compression was assessed using a myotonometer (probe area of 1 cm, speed 1 mm/sec, protrusion 3 mm) first in a relaxed condition and then at 2.5%, 5%, 10%, 15%, 20% and 30% maximal voluntary contraction (MVC) levels.

Results: At rest (P<0.001, Fig. 1B) and at 2.5% MVC (P=0.019), the curved path of the tendon provided longer lengths than the linear one. Already at 5% MVC the patellar tendon followed a linear path and thus linear distance between patellar and tibial attachment sites may be used when assessing e.g. mechanical properties of tendon, which are typically examined at forces above 10% MVC. Myotonometer peak force correlated with the level of knee extension torque (r=0.90, P<0.001). Based on knee extension torque a linear trendline through 2.5%-30% MVC levels suggested that tendon slack ends at a length which is approximately 4.4% greater than that found at rest. However, a similar estimation based on the myotonometer force suggests only 2.8% tendon elongation at the point when it starts to resist force (Fig. 1).

Figure:



Conclusion: The study showed that estimates of patellar tendon slack length differ depending on whether knee extension torque or myotonometer force is used in the estimations. These results suggest that myotonometry is potentially useful for assessing patella tendon slack length. Moreover, the data suggest that force levels lower than 2.5% MVC are required to further examine this issue; these experiments are currently ongoing.

NEW TAPING METHODS FOR INCREASING THE MUSCLE STRENGTH.

Tsutomu Fukui [1,*] Takashi Kondo [2] Yuko Otake [2]

[1]Health Care Science, Graduate School, [2]Sports Management Center, Bunkyo Gakuin University, Tokyo, Japan

Introduction and Objectives: While the application of Kinesio tapes may have some therapeutic benefits, the usage of these tapes does not promote strength gains in healthy adults [1]. Kinesio taping did not result in changes in maximal grip strength in healthy subjects [2]. Meanwhile, application of therapeutic Kinesio taping is effective in improving isokinetic quadriceps torque [3]. Although there were lots of researches used the Kinesio Taping for muscle strength, the results have not coincided. It is still uncertain and controversial how to use the taping for muscle strength. We have researched skin movement during joint motion by three dimensional motion analysis system. It was called skin movement artifact and exhibited movement difference between markers on the skin and underlying bone. One of the factors of the artifact may be caused by the sliding at the superficial myofacial layer. In clinical settings, these sliding could be used for muscle exertion by using the new taping technique. We have used this new taping methods named *skin taping* for some years and have lots of effects to facilitate the muscle strength. For facilitating muscle strength, taping direction which should accommodate to the direction from insertion to origin of the muscle was critical importance. The aim of this study is to certain the effects of *skin taping* methods for increasing muscle strength.

Methods: Thirteen healthy male subjects participated in this study. Average age was 23 ± 2.3 years old, height was 171.6 ± 2.5 cm, weight was 58.0 ± 3.9 kg. Gluteus Maximus (; GM) of them used for the evaluation. We applied right GM to ascertain the application of the facilitative taping by *Primus* RS [BTE technologies, Baltimore, USA]. After getting used to the isokinetic contraction, subjects were asked their hip extend maximally at 30deg/sec, concentric mode, three times with five minutes interval. Four condition of Isokinetic evaluation were fulfilled. Condition1: Elastic tape was applied from insertion to origin direction and skin on the Gluteus was stretched. Condition2: Elastic tape was applied from origin to insertion direction and skin on the GM was slacked. Condition3: Dummy tape with no direction. Condition 4: No tape, the order of the condition was randomized. Differences in mean value were assessed with one way ANOVA and Bonferroni multiple comparison procedure.

Results: Mean value of Condition1 was significantly greater than any other conditions ($p < 0.01$) .

Figure:

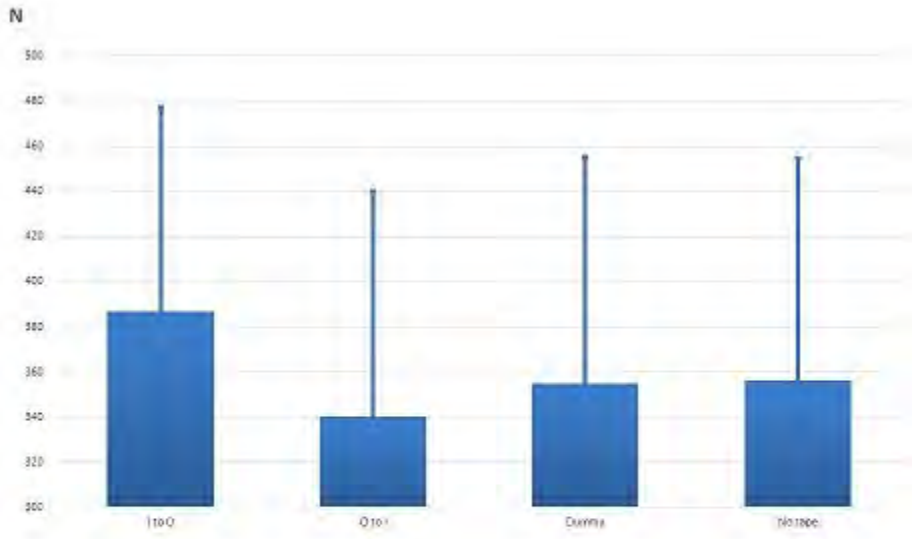

Fig. 1 Isokinetic strength of Gluteus Maximus
I to O was greater than any other taping conditions ($P<0.001$)

I to O: taping direction was from Insertion to origin O to I: taping direction was from origin to insertion.
Dummy: taping with no direction

Conclusion: New taping methods; *skin taping* facilitated the muscle strength. Skin taping direction run from insertion to origin direction may help the sliding of GM contraction. We could observe the sliding between GM and subcutaneous tissue at superficial myofacial layer by ultrasonography. We believe this direction is crucial and also reverse direction had a tendency of inhibition of muscle strength. New taping which run from insertion to origin direction increased the isokinetic GM muscle strength.

IMPACT OF FATIGUE ON CONSTANTS OF MOVEMENT FROM FORCE-VELOCITY RELATION AND ACTIVATION DYNAMICS

Harald Penasso [1,*] Sigrid Thaller [1]

[1]University of Graz, Institute of Sport Science, Graz, Austria

Introduction and Objectives: Muscles have properties that determine their characteristics at various conditions. From experience we know that the performance of muscles alters in the course of fatigue [1], and we generally assume that the physical condition of the muscles plays a major role to maintain a certain muscular performance. Therefore, the fresh state of the muscle should contain information about how the properties of the muscles change in the course of fatigue. The aim of this study is to calculate neuromuscular properties from non-invasive measurements in vivo. To identify these constants of movement we use nonlinear parameter identification strategies. A mathematical knee-extensor model is fitted to measured data sets containing data from explosive dynamic and isometric knee-extension maximum voluntary contractions (MVCs). The fatigue protocol is designed to allow the calculation of the constants minute by minute. At each stage we calculate a set of parameters that characterizes the force-velocity relationship (FV) of the knee extensors and its activation dynamics.

Methods: The original approach was introduced by Sust [2] and an improved method was published later [3]. Our recent modifications have enabled an automatized processing routine [4,5].

The model of a single leg-extension consists of an anthropometric-geometric function G(X) that transfers externally measured values to the corresponding values of the muscle and of a muscle force function including activation: $A(t) \cdot fm(vm)$. According to the individual FV the muscle force depends on the contraction velocity (vm) [6]. G(X) depends on position data (X) (distance from greater trochanter to lateral malleolus). The model output is the external force as a function of time.

Force data are measured at an inclined leg-press (9.8°) with a force plate mounted onto a sledge. The position of the sledge (X) is recorded by a high frequency position sensor. The anthropometric lengths of the leg used in G(X) are measured with a tape measure.

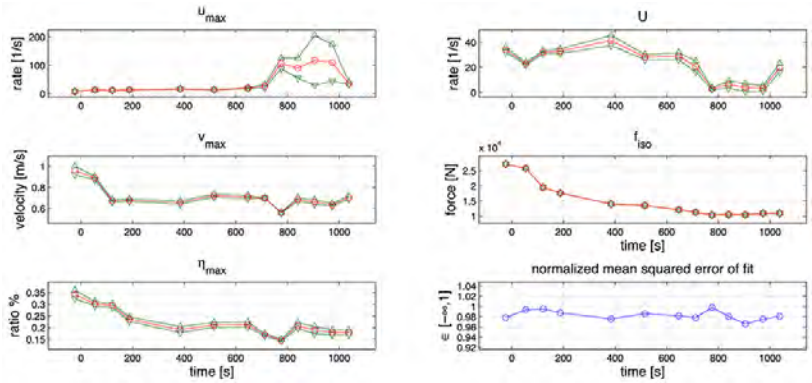
The parameter identification routine (Matlab) uses solvers for nonlinear functions to calculate the values of the arbitrary constants by minimizing the sum of the squared differences of measured force data and model output [5]. The constants are the maximum excitation (umax), the excitation rate (U), the maximum isometric force (fiso), the maximum contraction velocity (vmax), and the maximum efficiency (etamax). The final goodness of fit is determined via the normalized mean squared error (NMSE). The constants' confidence intervals, the correlation matrix, and the variance of each residual are calculated as well.

After briefing, familiarization, preparation, and warm up the experiment starts with four explosive dynamic concentric MVCs against the sledge (heels only)(2 conditions: 2x 53.5 kg and 2x 73.5 kg) and is followed by the fatigue protocol: $n \cdot$ [9 · (3 s isometric MVC followed by 3 s rest) plus two explosive dynamic contractions (73.5 kg and 53.5 kg) in quick succession]. The last series is reached individually when the decline of force stabilizes at around n = 15 repetitions.

For each series the constants of movement are calculated from data sets containing the 9th isometric MVC and the next two dynamic MVCs. The initial state is calculated from the first seven contractions where at least one of the two conditions is used.

Results: One subject completed n = 17 series where 13 series matched the inclusion criteria (no constant stuck in a constraint, NMSE greater than 0.96). From the initial state, umax increased by a factor of 4.5 whereas U declined to 58%, vmax to 73.4%, fiso to 40.5%, and etamax to 52.4%. This means that the curvature of the FV (a/fiso) increased to 239%. The mean of all included NMSE was 0.983 ± 0.00903.

Figure:



Caption: Fatigue related changes of constants of movement. U and umax refer to the activation dynamics and vmax, fiso, and etamax characterize the FV. Red o: final value, green ΔΔ: 95% confidence level.

Conclusion: We found that the model is able to reproduce fresh and fatigued states from non-invasive measurements at natural conditions of the movement. The findings in vmax and fiso are in accordance with literature but our findings show a different behaviour of the curvature of the FV (etamax, a/fiso) (cf. [1]). The planned combined analysis of kinematic data, EMG-data and the pooling of multiple subjects will lead to a better understanding of this fact.

Table:

	umax [1/s]	U [1/s]	vmax [m/s]	fiso [N]	etamax [-]	a/fiso [-]
fresh	8.08	34	0.959	27190	0.342	0.208
fatigued	36.2	19.7	0.704	11010	0.179	0.498

Caption: Fresh vs. fatigued values of the constants of movement.

EFFECTS OF STATIC STRETCHING AND PILATES METHOD IN ELDERLY WOMEN FLEXIBILITY: COMPARATIVE STUDY

Deise Aparecida de Almeida Pires-Oliveira [1,*] Rodrigo Franco de Oliveira [1] Raphael Gonçalves de Oliveira [1] Laís Campos de Oliveira [1]

[1] Masters and doctoral program in Rehabilitation Sciences, University of Northern Paraná, Londrina, Brazil

Introduction and Objectives: For the elderly, adequate levels of flexibility contributing to the achievement of activities of daily living independently. Among the possibilities of exercises for the development of this capacity, are static stretching and Pilates. However, there are no studies showing the differences between static stretching and Pilates on the flexibility of the elderly. Thus, the objective of this study was to compare the flexibility of elderly women subjected to static stretching and Pilates on flexibility variable.

Methods: This study is characterized as a randomized controlled trial, blind mono, with elderly residents in the community of the city of Jacarezinho, Paraná-Brazil. The project was approved by the Ethics Committee for Research involving human beings of North University of Paraná (Brazil) under the protocol 513.001.

Inclusion criteria were age between 60 and 65, are not practicing any kind of physical exercise in the last six months and agree not to do another type of exercise during the search. Exclusion criteria were: cognitive deficit>19 according to the Mini Mental State Examination, use of assistive devices for gait and/or presentation of musculoskeletal dysfunction.

After the initial selection, 32 volunteers were evaluated for their flexibility, and submitted to the randomization process, which distributed the volunteers in the stretching group (GA) and Pilates (GP), with 16 members each. After the speeches, they were reassessed.

To measure the flexibility we used a fleximeter assessing flexibility in degrees (°) in flexion (TFM) and trunk extension (EMT), hip flexion (HFM), plant (PFA) and dorse flexion of the ankle (DFA) in three attempts, and considered only the best.

The GA and the GP received 12 weeks of intervention carried out twice a week on nonconsecutive days lasting 60 minutes. The GA held 20 static stretching exercises for the major muscle groups, actively, in three sets of 30 seconds. The GP held 20 Pilates exercises, equipment: Combo Chair, Cadillac Trapeze, Universal Reformer and Ladder Barrel.

Statistical analysis was performed with SPSS 20.0 program, with a significance level of $p<0.05$. Verification of normality occurred using the Shapiro-Wilk test. The initial physical characteristics were compared using the Mann Whitney U test. Since it was not rejected normal distribution hypothesis, applied analysis of variance for repeated measures (ANOVA two way) to verify the intra and inter-group comparisons, at different times of the study. The post hoc Tukey was used for the identification of specific differences in variables.

Results: The groups showed no significant differences at baseline, the variables, age, weight, height and flexion and trunk extension, hip flexion and plant and dorse ankle flexion.

Table 1 shows the comparing pre and post intra-group intervention. The GA had a significant improvement to the TFM and HFM variables. For GP elderly significant improvement for all tests (TFM, EMT, HFM, PFA and DFA).

In the post-intervention comparison (between groups) there was no significant improvement to the TFM (p=0.553), HFM (p=0.873), PFA (p=0.623) and DFA (p=0.333). Only the assessment of EMT significantly different (p<0.001).

Conclusion: It was observed that older who underwent Pilates showed increased flexibility when compared to elderly who performed stretching and may be considered in clinical practice, when the objective is to increase the flexibility of older women.

Table:

Variables		Stretching Group (GA) n=16			Pilates Group (GP) n=16	
	Pre test	Post test	p-value	Pre test	Post test	p-value
TFM (°)	83,12±10,74	91,87±11,93*	0,0247	76,87±11,91	89,62±12,59*	0,0015
EMT (°)	21,32±6,92	24,06±6,60	0,0828	21,87±5,08	30,12±4,11*	<0,001
HFM (°)	88,81±11,73	98,37±7,24*	0,0473	81,56±20,16	99,12±17,48*	<0,001
PFA (°)	26,25±3,89	28,81±3,98	0,0977	24,56±6,03	28,06±5,76*	0,0255
DFA (°)	16,37±3,09	18,06±2,54	0,1057	16,81±3,51	19,06±2,64*	0,0328

Caption: Table 1. Mean values, standard deviation and α, when comparing pre and post-intervention (intragroup). NEUROMUSCULAR, BIOMECHANICAL AND COGNITIVE STRATEGIES: HOW CAN TAPE ALTER CONTROL?

Steven Lindley [1 2,*] Jim Richards [1] James Selfe [1]

[1]Allied Health Research Unit, University of Central Lancashire, Preston, United Kingdom, [2]Delsys Inc., Natick, United States

Introduction and Objectives:

Patellofemoral pain (PFP) is a musculoskeletal condition that has been described as “the Loch Ness monster of the knee” and the “black hole of orthopaedics” due to its indefinable and expansive nature when addressing the aetiology, management and treatment of pain in and around the knee cap. Although significant and clinically important changes have been observed with joint biomechanics, psychosocial factors, brain activity and neuromuscular activity there still remains a lack of understanding in the control of the knee and the efficacy of common clinical interventions.

This study aimed to provide a unique and multifaceted investigation into understanding the movement control of PFP subjects and the response to a common clinical intervention; explicitly studying the novel aspects of motor unit and neuromuscular control in combination with 3D joint kinematics and kinetics and complimentary clinical measurements of psychosocial characteristics. Consequently providing insight into the muscle force and control strategies both within and between muscle groups in and around the knee, including their response to a clinical intervention, whilst concurrently monitoring the knee joint biomechanics and cognitive measures.

Methods: Both non-symptomatic (n=13) and symptomatic subjects (n=13) performed a single limb isometric squatin two conditions, no tape and with a medial glide tape application. Motor unit data from the Vastus Medialis (VM) and Vastus Lateralis (VL) was recorded using sEMG Decomposition technology (Delsys dEMG). Muscle activity of the Gastrocnemius (GAS), Rectus Femoris (RF), Biceps Femoris (BF) and Gluteus Medius (GMed) were collected using sEMG (Delsys Trigno). Lower limb joint kinematics and kinetics was recorded at 200Hz and 2000Hz respectively, modelled using the CAST method. Measures of conscious motor processing were made using the Movement Specific Reinvestment Scale and pain levels recorded using the Numerical Rating Scale for the symptomatic subjects.

Results: Grouped Tape Response: Regression analysis of the mean motor unit firing rate against the knee joint sagittal joint moment showed the motor unit recruitment intercept was significantly higher and the recruitment slope significantly steeper in the VM for the non-symptomatic subjects with no change in the VL and no change in the symptomatic subjects. Both subject groups demonstrated significant reductions in transverse plane knee joint range of moment, no significant changes in the coronal or sagittal joint mechanics were found. Symptomatic subjects demonstrated a propensity to consciously control their movements and exhibited pain scores of 4.2/10 on the numerical rating scale.

Comparison of groups: Regression analysis comparing the subject groups, demonstrated that symptomatic subjects had a significantly flatter slope for the VM and VL compared to non-symptomatic subjects, and thus significantly different motor unit recruitment strategy. Symptomatic subjects demonstrated a lower common drive in the VM and higher common drive in the VL compared to non-symptomatic subjects. Symptomatic subjects also exhibited significantly lower muscle activity in the GAS, BF, RF and GMed. No changes were seen in the joint biomechanics between the groups.

Individual Tape Response: Exploration of individuals' response to tape exhibited a non-uniform response with variable increases, decreases and no changes across all the different measurements taken.

Conclusion: These findings suggest that the nervous system has various schemes to control the motor unit pool to the Vasti and how it responds to a taping intervention. However, it is evident that the motor unit firing rate, common drive and motor unit recruitment present variable responses amongst individuals, offering a portfolio of solutions to achieve the same goal; increasing the force and its control within the muscle. The underlying mechanism for the observed findings are unable to be expressed definitively, however it can be deduced that the application of tape presents feedback to the muscle that alters the motor unit pool; consequently adjusting the force and its control within and across muscles leading to an increase in knee stability.

The key clinical implications is that the application of tape can offer clinically meaningful change to the sensory-motor control system. However, researchers and clinicians should consider the individualistic responses with data analyses and clinical decision processes respectively.

INSERTION OF A PRESSURE SENSOR MINIMALLY AFFECTS HIND FOOT JOINT KINEMATICS DURING IN-VITRO GAIT SIMULATIONS

Tassos Natsakis [1,*] Josefien Burg [2] Greta Dereymaeker [1] Ilse Jonkers [2] Jos Vander Sloten [1]

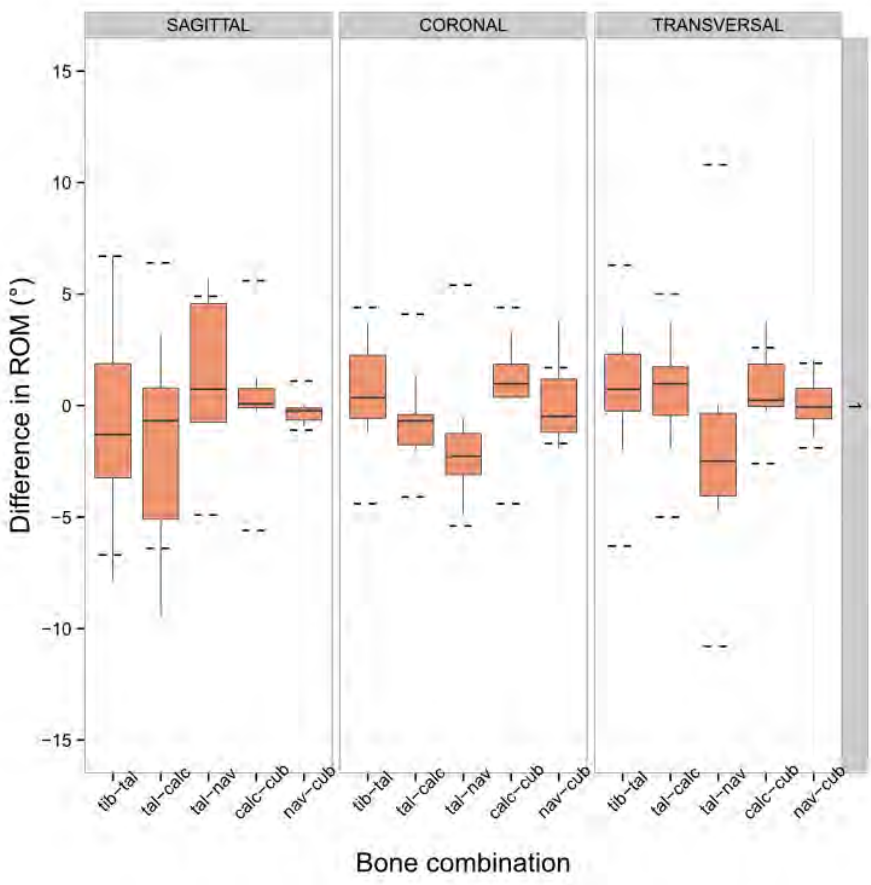
[1]Biomechanics section, [2]Faculty of Kinesiology and Rehabilitation Science, KU Leuven, Leuven, Belgium

Introduction and Objectives: Investigating joint loading is of high importance, as several pathologies of the hind-foot (e.g. ankle Osteoarthritis) have been linked to mechanical overloading. Different techniques exist to estimate the contact area or joint contact forces in-vivo, however when a direct measurement of the intra-articular pressure distribution is needed, it must be assessed with the insertion of a pressure sensitive array in the ankle joint. As this requires a highly invasive technique, it might potentially influence the biomechanical behaviour of the joint, more specific altering the kinematics and therefore changing the pressure distribution. Currently, however, the influence of a pressure sensitive array insertion on the resulting kinematics of individual joints was not previously documented. We therefore evaluated the influence of inserting the sensing array in the ankle joint on the range of motion (ROM) of individual joints of the hind-foot during in-vitro gait simulations.

Methods: Gait simulations were performed in 7 cadaveric specimens, amputated mid-tibially [1,2]. The tibial kinematics in the sagittal plane were imposed and the force on nine tendons was applied simulating roll-offs of one second duration. The kinematics of hind-foot bones were captured by an optoelectronic camera system (Krypton K600, Metris, Leuven, Belgium). Active LED markers were mounted on intra-cortical pins that were inserted in the tibia, talus, calcaneus, cuboid and navicular bones of each specimen. Gait simulations were performed before and after the insertion of a Tekscan #5033 (Tekscan Inc, Boston, MA) pressure sensor in the ankle joint. The ROM of each joint was calculated for each direction and a non-parametric rank sum test (Wilcoxon) for each joint and direction was performed between the two sets of measurements. Finally, the relevance of the difference in ROM was evaluated by comparing it with the normal variability in ROM measured in the specimens before the sensor insertion

Results: The maximal difference in ROM measured found in the talo-navicular joint for the transverse and coronal planes (3.2 and 1.6 degrees decrease respectively) and for the talo-calcaneal joint (1.2 degrees decrease). The difference in ROM measured for the tibio-talar joint was less than 1 degree in all three planes. None of these differences was statistically significant and was within the normal variability in ROM that was measured during the simulations before the sensor insertion.

Figure:



Caption: Difference in range of motion (ROM) for all specimens for each bone combination and plane of motion (positive means increase). The width of each box represents the interquartile range, while the bottom and top end of the whiskers represent the lowest and highest value still within 1.5 of interquartile ranges respectively. The horizontal line inside the box represents the median. The horizontal dotted lines represent the one standard deviation of the ROM in all the measurements without the sensor.

Conclusion: After sensor insertion , differences in ROM are non significant and fall withing the normal variability of the ROM. This, suggests that the kinematics of the hind-foot are not affected by the insertion of the pressure sensing array used in this study. Therefore, such sensing devices can be used to accurrately assess representative joint loading conditions during simulated gait.

GLUTEAL MUSCLE ACTIVATION PATTERNS AND HIP JOINT MOTION ARE ALTERED IN THOSE WITH MODERATE AND SEVERE HIP OSTEOARTHRITIS COMPARED TO ASYMPTOMATIC COHORT

Janice Moreside [1 2,*] Derek Rutherford [1 2 3] Ivan Wong [4]

[1]Kinesiology, [2]Physiotherapy, [3]Biomedical Engineering, [4]Orthopaedic Surgery, Dalhousie University, Halifax, Canada

Introduction and Objectives: End-stage (severe) hip osteoarthritis (OA) has been the focus of much biomechanical research, yet little is known as to how joint mechanics alter with increasing severity during gait. Similarly, motor patterns of the surrounding musculature has not been explored among those of increasing hip OA despite increasing support for the role of such musculature to maintain hip function during functional activities. Thus, the purpose of this study was to compare gluteal muscle activation patterns and 3-dimensional hip joint kinematics between 3 groups: those with 1) advanced, 2) moderate unilateral hip OA, and 3) an asymptomatic cohort.

Methods: 60 participants were recruited: 20 with moderate OA and 20 with severe OA, as determined by requirement for surgical management by an orthopaedic surgeon (arthroscopy (moderate) vs. arthoplasty (severe)). Kellgren-Lawrence classifications were used for radiographic OA grading. 20 age-matched asymptomatic participants were recruited from the community. Preferred walking speed was determined using the Gaitrite™ instrumented walkway, followed by approximately 10 minutes of treadmill walking at the determined speed, during which 3 - twenty second trials were collected.

Gluteus maximus and medius electromyograms (EMG) were recorded according to a standardized protocol at 2000 Hz using a custom LabVIEW™ program. Raw signals were processed using custom MATLAB™ script resulting in a linear enveloped signal, normalized to peak amplitude obtained during the gait cycle.

Hip joint 3D kinematics were collected at 50 Hz using a Qualisys® motion capture system. Joint angles were calculated using a 6 degree of freedom model with Cardan/Euler rotations (sagittal, frontal, axial sequence). Heel strike events were determined using an established kinematic method.

Joint angles and EMG were time normalized to 100% of the gait cycle and ≥40 individual waveforms were ensemble averaged to create one waveform per individual. Principal component analysis (PCA) extracted electromyographic waveform features. From 3D hip motions, discrete measures (maximum, minimum) and angular excursions were calculated. A series of one way ANOVAs determined between group differences ($\alpha=0.05$) for 3-dimensional hip motions and principal component scores, with Tukey's post-hoc tests when appropriate.

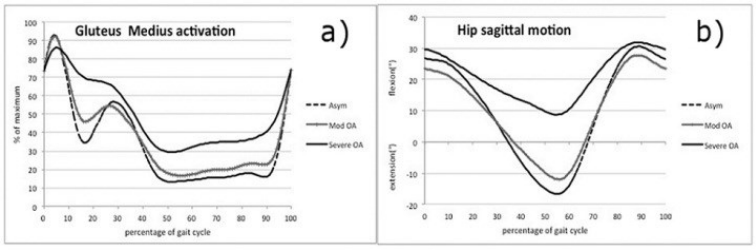
Results: The severe OA group used a smaller range of total motion (maximum – minimum range) in all 3 planes, compared to both the asymptomatic and moderate groups ($p<0.026$). In the sagittal plane, total motion utilized by the moderate OA group was also significantly different than the asymptomatic group ($p=0.002$) (Figure 1a). The severe OA group demonstrated less hip extension and adduction than either of the other groups ($p< 0.001$), and less hip external rotation than the asymptomatic group ($p<0.019$).

In the severe OA group, gluteus medius demonstrated less dynamic response to changing loads throughout the gait cycle, compared to the other 2 groups (Figure 1b). Instead, the gluteus medius initial peak response to heel strike was

lower, followed by higher levels throughout the rest of the cycle, especially mid-stance. This was corroborated by significant differences between the severe and other two groups for both PC1 and PC2 ($p<0.005$), identifying temporal between-group differences. Average EMG patterns indicate the moderate OA group also showed a trend towards the gluteus medius pattern seen in the severe group (Figure 1b).

Similarly, gluteus maximus activation in the severe OA group showed an initial lower response to heel strike, following by higher activation throughout stance, especially mid-stance. PCA indicated temporal differences between the severe and asymptomatic groups ($p=0.05$).

Figure:



Caption: Figure 1: a) Average amount of hip flexion (+ve) and extension (-ve) utilized during the gait cycle by the 3 groups studied. b) Gluteus medius activation throughout the gait cycle as a percentage of maximum amplitude obtained during the gait cycle.

Conclusion: As 3-dimensional hip motion during gait diminishes with increasing hip OA severity, gluteal muscle activation patterns also change, particularly during early and mid-stance. While these findings occur in those with severe OA, the moderate OA group also showed similar changes in gluteus medius. These increased contraction levels during gait would likely increase compressive forces within the hip joint, potentially hastening further joint deterioration and diminished function during gait.

Table:

	age	BMI[a]	velocity[b]	KL score
Asym	62.6(6)	25.6(5)	1.5(0.2)	-----
Mod OA	59.1(8)	28.7(4)	1.3(0.2)	2
Severe OA	63.4(8)	30.5(5)	1.1(0.2)	4

Caption: Table 1: Participant demographics and average Kellgren-Lawrence (KL) score. a= significant difference between the asymptomatic and severe groups ($p=0.026$). b= significant differences between all groups ($p<0.015$)

TEXTURE ANALYSIS OF ULTRASOUND IMAGES ON THE QUANTIFICATION OF THE MUSCLE DAMAGE INDUCED BY ECCENTRIC EXERCISE

Thiago T. D. Matta [1,*]Wagner Pereira [1]Regis Radaelli [2]Ronei Pinto [2]Liliam Oliveira [1]

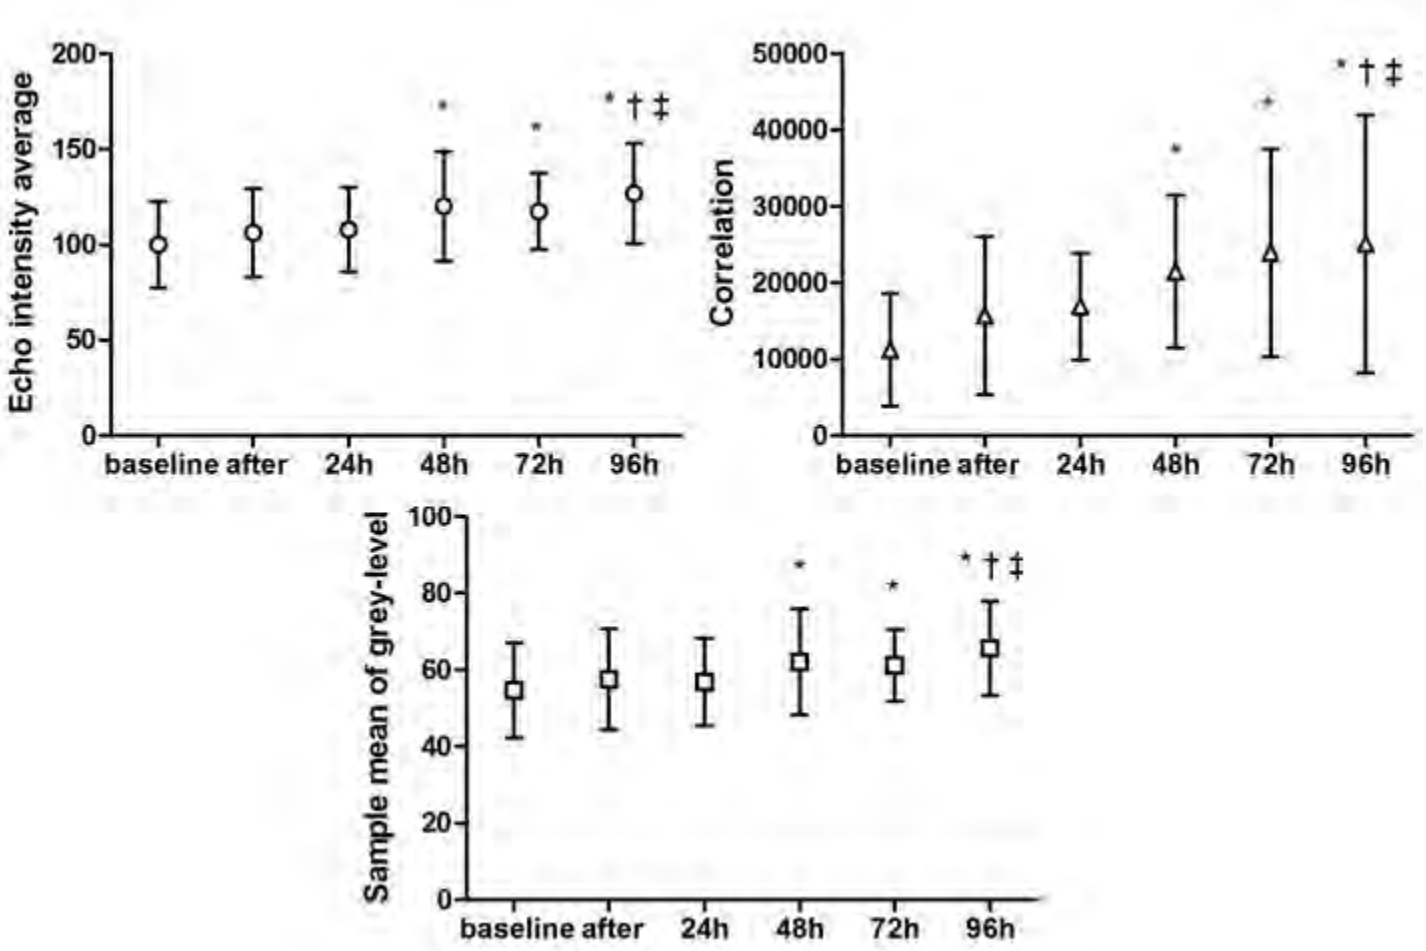
[1]Biomedical Engineering Program, Federal University of Rio de Janeiro, Rio de Janeiro, [2]Laboratório de Pesquisa do Exercício, Federal University of Rio Grande do Sul, Porto Alegre, Brazil

Introduction and Objectives: High intensity or volume eccentric muscle contractions induce skeletal muscle damage, mainly when the subject is untrained (1). There are many techniques to evaluate the physiological effects of those types of exercises and to quantify of consequent muscle damage (2). Ultrasound echo intensity is commonly used as a local and non-invasive method, and it is based on the histogram of the greyscale pixels of a region-of-interest (ROI) (3). However the small order of the image unidimentional analysis and impaired spatial assessment of the ROI must be considered technical limitations (4). Image texture analysis is a mathematical procedure used to inform the relative position between pixels of the ROI and quantified by many statistical techniques (e.g. grey-level of co-occurrence matrix – GLCM or complexity curve – CC) (5). Therefore, texture analysis can be a promising method for muscle damage studying, which has not been reported in literature yet. The aim of the present study is to analyze the time changes of the complexity curve and grey-level co-occurrence matrix texture parameters and echo intensity on ultrasound images of Brachialis muscle during volume eccentric muscle contractions.

Methods: Thirteen healthy young women performed two sets of ten elbow flexors eccentric contractions by elbow joint extensions at 30 degrees/second, with a 60-second rest interval. The images were acquired by B-mode ultrasound (Nemio XG, Toshiba, Japan, 7.5 MHz, 38 mm linear probe), at 8 cm above the elbow joint. Ultrasound images were acquired at baseline, immediately after, 24h, 48h, 72h and 96h after exercise. Ten texture parameters were calculated: five for GLCM: entropy(*coo*), second angular moment (*asm*), standard deviation (*std*), contrast (*con*)and correlation (*cor*); and five for CC: maximum value (*mv*), average value (*av*), sample mean of grey-level (*sm*), sample standard deviation of the grey-level (*ssd*) and entropy (*ent*). The echo intensity value was considered de mean and median values of the gray distribution (0: black and 255: white). All parameters were calculated on a ROI of 25 x 25 pixels of the brachialis muscle.

Results: Significant value increase was found for the *cor, sm* and echo intensity average at 48, 72 and 96h from baseline, and 96h from immediately before and 24h (Figure 1). Other parameters do not differ statistically. The *cor* increasing presented a high similarity between grey levels, and this response can be visually assessed by changes in brightness on ultrasound images after few days of high intensity eccentric exercises. The *sm* emphasizes grey levels that present large number of transitions on binary image. A heterogeneous texture tends to result in high *sm* values and is dependent on grey-level adopted on image processing, and it is clearly numbers of grey-level dependent.

Figure:



Caption: Figure 1: Mean and SD of correlation, sample mean of grey-level and echo intensity average. * for $p < 0.05$ from baseline; † for $p < 0.05$ from after; ‡ for $p < 0.05$ from 24h.

Conclusion: The texture analysis by the GLCM and CC seems to be a useful tool of assessing muscle damage as well as different biological tissues. The *cor* and *sm* proved to be the most sensitive and promising single texture parameters to study time changes of muscle damage as verified after 48h. Additional studies must include the evaluation performance for associated parameters as well as for different number of grey levels and ROI sizes and site selection, muscles with different fiber arrangement or ultrasound probe orientation.

MULTI-JOINT MODELING: EFFECT OF KNEE MUSCLE IMBALANCE ON SACROILIAC JOINT STRESS LEVELS DURING THE STANCE PHASE OF GAIT

Jerome Hausselle [1,*] Roger V. Gonzalez [1]

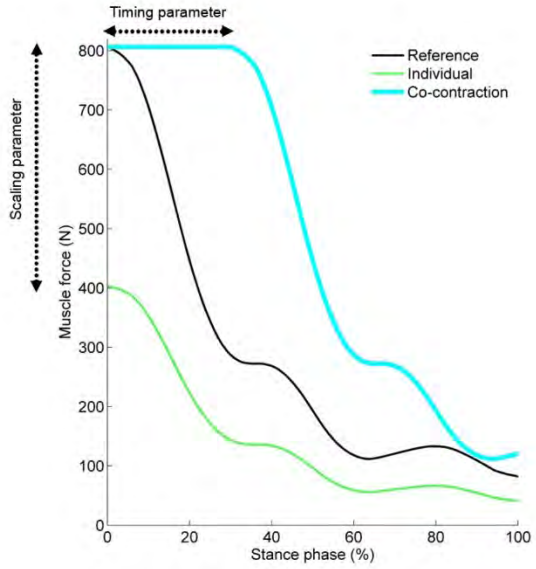
[1] Mechanical Engineering, The University of Texas at El Paso, El Paso, United States

Introduction and Objectives: Degenerative joint diseases such as osteoarthritis (OA) usually lead to the development of compensatory mechanisms to limit pain. For example, knee OA often increases the risk of comorbidities such as low back pain and OA onset in adjacent joints [1]. Although many current studies focus on understanding OA onset and development, to our knowledge, none focuses on comorbidity issues. There is for example a dearth of information regarding potential effects of knee compensatory mechanisms on hip and sacroiliac joints. To bridge that gap, we developed a computational multi-joint model to study the effect of knee extensor and flexor individual muscle forces and co-contractions on the sacroiliac joint stress levels during the stance phase of gait.

Methods: We developed a finite element model of the hip-pelvis system in FEBio [2]. Our model included the hip, pubic symphysis, and sacroiliac joints; and nine muscles crossing the hip and/or knee joint. The bones (femoral head, ilium, and half of the sacrum) were considered as rigid bodies and were joined by the hip, sacroiliac, and pubic symphysis cartilages. Cartilage was defined as an isotropic elastic material and seven sacroiliac ligaments were modeled using tension-only springs [3]. The sacrum bone was fully constrained, as well as the medial face of the pubic symphysis cartilage. Input kinematics and kinetics data were taken from published studies [4-6] and we computed the muscle force orientations throughout the motion by combining the femoral kinematics data with a lower limb model previously developed [7]. The mean von Mises stress of reference throughout the motion was computed with all the muscle forces scaled at 100%. Then, for each of the four muscles of interest (Rectus Femoris, Biceps Femoris, Semimembranosus, and Semitendinosus), eleven simulations were performed by scaling the force curve between 50 and 150%, with 10% increment. Then, co-contractions were simulated by modifying he contraction timing of the Biceps Femoris muscle, *i.e.* increasing the duration of the maximum force developed from 10 to 50% of the stance phase of gait, with 10% increment (see figure). Relative stresses were computed as the percentage of the difference between each mean von Mises stress with the mean stress of reference divided by this reference value.

Results: Results on individual muscle force showed that only the Biceps Femoris muscle force levels influenced the sacroiliac joint stress level (see Table). This result can be explained by the location of its insertion on the ilium, combined with the fact that it developed the highest force of all the muscles included in the model. Co-contraction simulations highlighted the fact that joint stress levels seemed to be as sensitive to co-contractions as to individual muscle forces, at least regarding the Biceps Femoris.

Figure:



Caption: Examples of Biceps Femoris muscle force curves: reference (black), individual contraction curve (dashed green) with a scaling parameter of 50%, and co-contraction curve (cyan) with a timing parameter of 30%.

Conclusion: There is a need to understand potential consequences of compensatory mechanisms due to degenerative joint diseases at the whole body level. We showed that individual muscle force modifications and co-contractions developed to cope with a specific joint issue affect stress levels in adjacent joints. We believe that this multi-joint approach will pave the way for novel computational studies focusing on modeling entire kinetic chains. Follow-up work will include taking into account kinematic changes due to muscle force changes, adding more muscles, and studying more in details the effects of co-contractions. Such models will enable us to assess the efficiency of rehabilitation protocols and pain management strategies at the whole body level, and minimize the risk of comorbidities.

Table:

IN VIVO STATIC AND DYNAMIC DEFORMATION OF ARTICULAR CARTILAGE

Ziad Abusara [1,*] Markus Kossel [1] Walter Herzog [1]

[1]Human Performance Lab, University of Calgary, Calgary, AB, Canada

Introduction and Objectives: *In vivo* movement of bones comprising synovial joints has been evaluated in various ways and has been calculated theoretically to understand joint biomechanics. In order to assess joint loading and bone movements accurately, the deformation behavior of articular cartilage has been investigated in confined and unconfined compression experiments and indentation tests, but to date there exist no data on dynamic *in vivo* deformation of articular cartilage in intact joints loaded through controlled muscular contraction. Therefore, the aim of this study was to measure in vivo, real time articular cartilage deformations for precisely controlled static and dynamic muscular loading in intact joints.

Methods: In order to achieve the purpose of this study, we developed a novel *in vivo* testing system that allows for controlled loading of mouse knees through muscular contractions and quantification of the associated, cartilage and chondrocyte deformations. Mice (n=12) were fixed in a custom-built jig onto the stage of a dual photon microscope. Controlled forces of the knee extensor muscles were produced through direct muscle stimulation using indwelling fine wire electrodes and a Grass (S8800) stimulator. Static loading was applied over an 8s period using muscular forces of up to 80% of the maximal possible knee extensor force. Dynamic loading was applied using 15 repeat contractions lasting 0.5s each and repeated every 4s using forces ranging from 40-80% of maximal. The medial meniscus was excised to provide a direct view of the medial tibio-femoral joint. Imaging of articular cartilage deformation across the entire medial compartment of knees was performed using a Zeiss 40×0.95 NA water-immersion objective coupled with a Coherent Chameleon IR laser tuned at 780 nm for two-photon excitation.

Results: *Single static load*

The average overall cartilage thickness was 32±2 μm on the femoral condyles. Increases in muscular loading of the knee caused increases in articular cartilage deformation (Figure 1c). 80% of the maximal muscular forces (equivalent to twice body weight) produced average peak articular cartilage strains during an 8s contraction of 18.3±1.5% (Mean ± SD) (Figure 1a). Cartilage peak deformation was reached at the end of force application. Cartilage tissue recovered to its original thickness within approximately 45s following force removal (Figure 1a).

Dynamic cyclic load

Articular cartilage compressive strain increased as a function of muscular load (Figure 1c). 80% of the maximal muscular forces produced average peak articular cartilage strains of 10.7±1% (Mean ± SD) (Figure 1b). Cartilage deformation, for these conditions, started at the 4th muscular contraction and reached its maximum by the end of the last pulse. Cartilage tissue recovered to its original shape within approximately 35s following force removal (Figure 1b).

Figure:

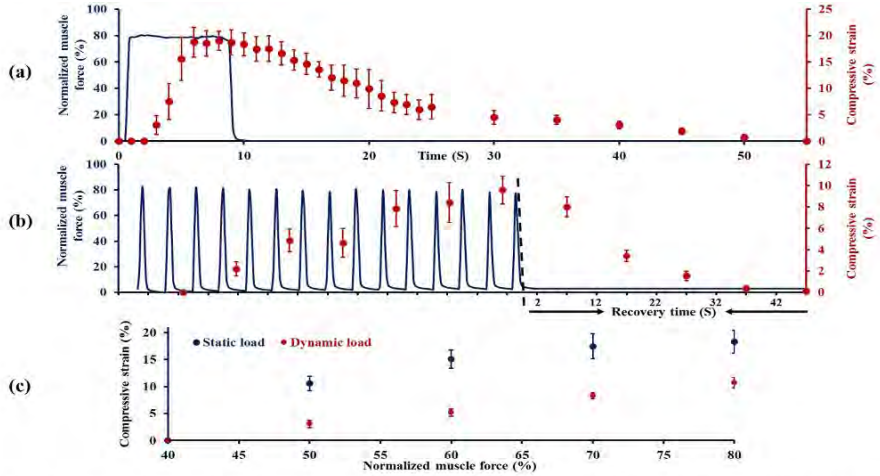

Figure1: (a) Normalized (relative to maximum =100%) knee extensor forces as a function of time. Muscles were stimulated for 8s at a voltage and frequency producing approximately 80% of the maximal isometric force. Cartilage deformation changes during loading and recovered to its original shape within approximately 45s following force removal (n=7) (b) Normalized muscle force as a function of time. Muscles were stimulated for 0.5s every 4s using a current and frequency producing approximately 80% of the maximal force. Cartilage strain increased with increasing the number of muscular force pulses. Cartilage tissue recovered to its original shape within approximately 35s following force removal (n=5) (c) In the static load condition, Articular cartilage strain increases exponentially between about 40 – 70% of the maximal force, and remains almost constant beyond about 70 - 80% of maximal force. In case of dynamic load, cartilage strain increases almost linearly. No sign of cartilage deformation was noticed at a 40% of maximal force or less.

Conclusion: The results of this study suggest that tibio-femoral contact between the articulating surfaces is only achieved with relatively high muscular forces (about 40% of maximal). This may be an artifact of the current setup where the medial meniscus was removed, and physical contact between the two articulating surfaces may occur for lower forces if the meniscus had been left intact. This finding will need to be investigated further. However, this result suggests, that in the presence of medial meniscectomy, high forces are required to obtain physical cartilage to cartilage contact in the medial tibio-femoral compartment of the mouse knee. Cartilage behaves highly visco-elastically. Specifically, peak cartilage deformation is reached much later than peak joint loading through the muscle forces. Here, we found that peak cartilage deformations were always reached at the end of the 8s loading time or at the end of the 15th muscular contraction, suggesting that cartilage deformation would have been greater than found here had joint loading been applied for longer than 8s or more than 15 loading cycles. This visco-elastic cartilage deformation behavior suggests that in normal cyclic movements, such as walking (loading time of approximately 800ms) peak steady-state cartilage deformation corresponding to the applied force is not reached within a few loading cycles. Similarly, full cartilage thickness recovery following load removal takes approximately 40s, suggesting that deformation recovery within cyclic movements such as walking, with an unloading time of about 1s, may be neglected. Finally, peak cartilage deformation for the static loading conditions seems to reach its maximum at muscle forces of about 70% of the maximal isometric force, with further deformations with higher forces not detected by our system. This begs the question of stiffness changes in cartilage with increasing loads and the mechanisms underlying extreme deformation of cartilage under very high joint loading conditions.

DEVELOPMENTAL DIFFERENCES IN MUSCLE FASCICLE BEHAVIOUR DURING WALKING: IMPLICATIONS FOR MOVEMENT EFFICIENCY?

Charlie M. Waugh [1,*] Nicola Theis [2] Thomas Korff [1] Bill Baltzopoulos [1]

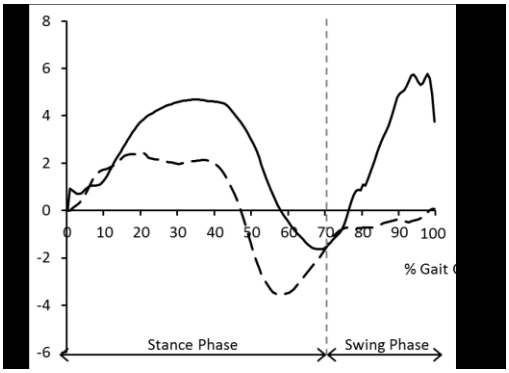
[1]Sport, Health and Exercise, Brunel University, Uxbridge, [2]School of Sport Health and Applied Sciences, St Mary's University, Twickenham, United Kingdom

Introduction and Objectives: Children perform cyclic motor tasks less efficiently than adults; however, the mechanisms underlying such differences are not fully understood. One mechanism that may contribute to age-related differences in task efficiency is the fascicle behaviour of key muscle groups in relation to the velocity of the movement outcome, as this can influence the muscle's energy expenditure and power output. Differences between children and adults have been identified in both tendon stiffness and the interaction between muscle and tendon within a muscle-tendon unit, both of which may affect fascicle mechanics and could influence movement efficiency. The primary aim of this study was to examine muscle fascicle length changes during steady-speed preferred walking velocity between children and adults to elucidate the mechanisms of muscle energetics

Methods: 4 children (9.5±1.5 years) and 4 adults (27.9±2.7 years) walked unshod on an instrumented treadmill at 80% of their preferred over-ground walking speed (0.66 and 1.07 ms-1, respectively; [1]) for a 10-minute period. Reflective markers placed on the hip, knee and foot provided lower body movement kinematics. Gastrocnemius Medialis (GM) fascicle length changes were visualised using ultrasonography and quantified using an automatic tracking algorithm [2, 3]. Fascicle length changes were averaged over six consecutive walking steps for each participant, determined by the treadmill ground reaction forces, and normalised to the average fascicle length of the trial (Figure 1). Peak shortening, peak lengthening and mean fascicle velocities were calculated from the stance phase data of the gait cycle (0 – 70% gait cycle) only. Group means of velocity data were examined using an independent t-test ($p<0.05$).

Results: Mean fascicle length for children and adults was 38.5 ± 6.8 and 47.9 ± 4.4 mm, respectively. Children appeared to demonstrate a greater fascicle lengthening, relative to normalised fascicle length at heel strike (0% gait cycle), during the ground contact phase of the step cycle. Despite this, peak shortening, peak lengthening and mean fascicle velocity was not different between children and adults (Table 1).

Figure:



Caption: Figure 1. GM fascicle length changes in children (solid line) and adults (dashed line) during treadmill walking. Fascicle length changes are expressed in relation to gait cycle and as a percentage of the mean fascicle length calculated across the duration of the walking trial.

Conclusion: The present data demonstrate that GM fascicle velocities are similar in children and adults during unshod treadmill walking, which might indicate that the muscle's energy expenditure during preferred walking velocity is comparable between groups, in relation to fascicle length effects. The overall behaviour in GM fascicle mechanics may be different between groups, indicated qualitatively by their different lengthening and shortening profiles. These results may have implications for muscle power and so may influence movement strategies and sporting performance.

Table:

	Children	Adults	P-value
Peak Shortening Velocity	-0.46 ± 0.16	-0.55 ± 0.15	0.935
Peak Lengthening Velocity	0.71 ± 0.33	0.82 ± 0.09	0.449
Mean Fascicle Velocity	0.02 ± 0.02	0.02 ± 0.05	0.526

DYNAMICS OF NEWTS LOCOMOTION ON INCLINES

Aihong Ji [1,*] Benzheng Dong [1] Zhendong Dai [1]

[1]College of Astronautics, Nanjing University of Aeronautics and Astronautics, Nanjing, China

Introduction and Objectives: In the learning of locomotion behavior of newts, the seeked principle of its locomotion can be an important inspiration on the design of robot of wet adhesive mechanism. To achieve this goal, in this paper, locomotion behavior of newts on surfaces of 0^0 , 30^0 , 60^0 and 75^0 are recorded. Hereby, variation in spatial and temporal kinematics of different surfaces' locomotion is analyzed.

Methods: Newt (*Pachytriton labiatus*), from Guangxi, China, were used in experiment (4.82±0.73g mass, snout-vent length: 53.76±2.34mm, mean ± s.d.,N=10). The newts were train to move through the aisle of the force measuring array (FMA). The FMA was rotated step by step (30° per step) to imitate different incline surfaces. Synchronously to the force measurement (500Hz), a high speed camera (iSpeed-3, Olympus,1280×1024 pixels) recorded each trial at 25 Hz. Moving behavior results from the continuous force action, so impulse of the forces were introduced to present the force effects. The microstructure of pad observed by SEM is used to analyze its role for wet adhesion.

Results: The moving speed of newts decreased with incline angle. The duty factor of locomotion is gradually increased by the incline slope, it is 0.73 when climbing on the level and 0.92 when crawling on 75^0 surface. The lateral force impulses I_L acting on the front and hind limbs increased with respect to inclines, and the I_L acting on front limb increased faster than that acting on hind limb. The results suggest that lateral force become more important on larger slope inclines. The fore-aft impulse IF acting on front limb increases with increase of incline. The front limb generated negative F_F when newt move on horizontal surface, which suggests that the front limb plays an important role as a brake on horizontal surface while playing a role of propulsion on non-horizontal surface. The hind limb generated positive IF that appeared to act as a source of propulsion over the range of the incline angle from 0° to 75°. The front limb provided negative normal impulses F_N to pull the center of mass toward incline when inclines were larger than 60°. The microstructure of newts' pad be similar with tree frogs', this structure contributes to increase shear force and reduces the stiffness to increase contact area.

Conclusion: The climbing velocity gradually decreases with increasing the degree of slope, but step lengths no significant difference, so newts mainly moderate the pace by stride frequency rather than step length. Duty factor growing shows that newts need more contact time to maintain the stability and continuity for locomotion. The front and hind legs' function vary with increase of degree of slopes, forelimbs change from complementary role to main exporter of driving force. Lateral force toward body sides can form adduction force being similar to newt's pattern, this is beneficial to increase shear force and reduce the height of mass center to decrease the pitching moment. Adhesion force is far less than peeling force, so newts can't climb on a vertical surface.

ULTRASONIC SHEAR-WAVE ELASTOGRAPHY STUDY ON THE EFFECT OF ELEVATION ANGLE IN CROSS-BODY STRETCH

Jun Umehara [1,*]Satoshi Hasegawa [1]Satoru Nishishita [1]Masatoshi Nakamura [2]Hiroki Umegaki [1]Takuya Kobayashi [1]Hiroki Tanaka [1]Kosuke Fujita [1]Noriaki Ichihashi [1]

[1]Human Health Sciences, Graduate School of Medicine, Kyoto University, [2]Faculty of Health and Sports Science, Doshisha University, Kyoto, Japan

Introduction and Objectives: Cross-body stretch, which induces horizontal adduction of the shoulder, is often performed to prevent posterior shoulder tightness, as it is thought that such tightness is a contributing factor of shoulder injuries. Wilk et al. (2013) reported that cross-body stretch with stabilized scapula is more effective than that without stabilized scapula. However, there has been no investigation of the effect of the elevation angle of the cross-body stretch on posterior shoulder tightness.

Recently, a new ultrasound technology called ultrasonic shear-wave elastography (SWE) has allowed noninvasive and reliable measurement of the shear elastic modulus of a muscle. Nakamura et al. (2014) reported that the shear elastic modulus measured by SWE is a reliable index of the flexibility of an individual muscle.

The aim of the present study is thus to investigate the effect of the elevation angle on cross-body stretching using the shear elastic modulus measured by SWE as an index of muscle flexibility.

Methods: The nondominant shoulder of eighteen healthy male (age: 23.7 ± 3.4 years) subjects were evaluated. While side-lying on their dominant side, the subjects randomly performed cross-body stretch at three elevation angles; i.e., horizontal adduction at 60° elevation (60Ele), 90° elevation (90Ele), and 120° elevation (120Ele). This cross-body stretch was repeated five times for 30 s at 20 s intervals, over a total period of 150 s. The horizontal adduction angle during the cross-body stretch was defined as the maximum angle that the subjects could achieve without discomfort or pain. Before (Pre) and after (Post) cross-body stretch, the shear elastic modulus of the superior and inferior portions of the infraspinatus muscle (ISPs and ISPi), the teres minor muscle (TM), and the posterior portions of the deltoid muscle (Deltoid) were measured. Measurements were made using ultrasonic SWE (Axiplorer; SuperSonic Imagine, Axi-en-Provence, France). An ultrasound transducer (SL-10-2 linear ultrasound transducer) was positioned on measurement points parallel to the direction of the muscle fiber, which was confirmed by tracing several fascicles without interruption across the B-mode image. During the measurement, the subjects were in a seated position with their arm held at 90° shoulder forward elevation.

The shear elastic modulus of each muscle was analyzed by two-way analysis of variance (ANOVA) with repeated measures (factors: time ´ elevation angle). When a significant interaction or main effect of time was found, the level was assessed as the significance of difference using the paired Student's *t*-test with Bonferroni revision as a post-hoc test. Differences were considered statistically significant at an alpha level of $P < 0.05$.

Results: The results for the shear elastic modulus of each muscle at Pre and Post are given in Table. In the cases of ISPs and ISPi, ANOVA showed no significant interaction between time and elevation angle, but indicated a significant main

effect of only the time factor. The post-hoc test for time indicated that the shear elastic modulus of Post was lower than that of Pre for all elevation angles. In the case of TM, ANOVA showed significant interaction between time and elevation angle. The post-hoc test for the time factor indicated that the shear elastic modulus of Post was lower than that of Pre for 120Ele, whereas no significant difference between Pre and Post was found for 60Ele or 90Ele. The post-hoc test for the elevation angle factor indicated that the shear elastic modulus of 120Ele was lower than that of 60Ele and 90Ele for Post, whereas no significant difference between 60Ele and 90Ele was found for Post. In the case of Deltoid, ANOVA showed no significant interaction or main effect.

Conclusion: This current examined the effect of cross-body stretch on posterior shoulder structures, and showed that shear elastic moduli of ISPs and ISPi significantly decreased after cross-body stretch at all elevation angles. In the case of TM, the shear elastic modulus of Post for 120Ele was significantly lower than that of Pre. However, the shear elastic modulus in the case of TM for 60Ele and 90Ele showed no significant difference between Pre and Post. In the case of Deltoid, the study showed that the shear elastic modulus did not significantly decrease after stretching.Our study thus revealed that the flexibility of ISPs and ISPi increased after cross-body stretch at all elevation angles. However, only cross-body stretch at an elevation angle of 120° increased TM flexibility.

Table:

Muscle	Angle	Pre(kPa)	Post(kpa)	Interaction
ISPs	60°	6.6±1.6	4.9±1.6*	P=0.53
	90°	6.3±1.6	4.4±1.1*	F=0.66

CHANGES IN BIOMECHANICAL BEHAVIORS OF THE CERVICAL SPINE AFTER DEGENERATION OF THE INTERVERTEBRAL DISC AND FACET JOINT

Won Man Park [1] Dae Kyung Choi [1] Kyungsoo Kim [2] Yoon Hyuk Kim [1,*]

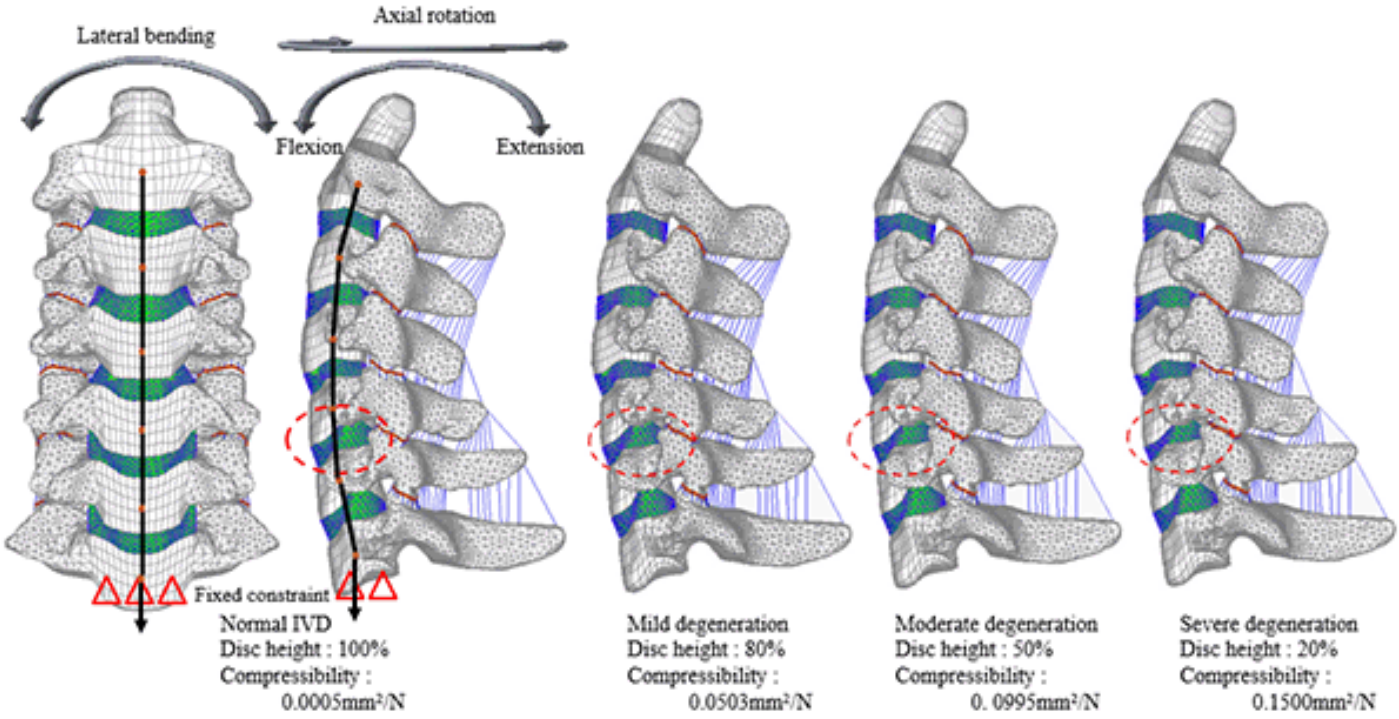
[1]Mechanical Engineering, [2]Applied Mathematics, Kyung Hee University, Yongin, Korea, Republic Of

Introduction and Objectives: Cervical disc degeneration is one of the most common causes of neck pain **[1]** and there is evidence that disc degeneration often accompanies facet joint degeneration **[2]**. It has been reported that facet joint degeneration is also considered an important source of pain in the cervical spine **[3]**. In this study, we developed finite element (FE) models of the cervical spine with various grades of intervertebral disc and facet joint degeneration. Then, changes in biomechanical behaviors including ROM, intradiscal pressure, and facet joint force at the degenerated and adjacent segments were investigated using the developed FE models.

Methods: A three-dimensional finite element model of the healthy cervical spine from C2 to C7 was developed based on a series of computed tomographic images. Then mild, moderate, and severe degenerations of the intervertebral disc and facet joint were described at the C5-C6 motion segment based on the clinical classification **[4, 5].** Disc height and artificial cartilage thickness decreased by 20%, 50% and 80% for mild, moderate and severe degeneration, respectively (Figure). Annulus fibrosis and ligaments were pre-stressed and/or buckled by the loss of disc height. And compressibility of nucleus pulposus increased with progress of degeneration. The developed FE models of the healthy and degenerated cervical spine were examined in hybrid loading conditions for flexion, extension, lateral bending, and axial rotation. Changes in segmental rotations, intradiscal pressures and facet joint forces at the degenerated and adjacent segments were investigated in this study.

Results: Segmental rotation of the C5-C6 motion segment during flexion-extension, left-right lateral bending, and left-right axial rotation decreased with progression of degeneration by 33% on average. Segmental rotations at the inferior and superior motion segments to the degenerated segment increased with progression of degeneration for compensating the decreased motion at the degenerated segment (Table). While intradiscal pressure at the degenerated segment in all motions decreased with progression of degeneration, the pressures at the adjacent segments slightly increased during flexion (Table), and slightly decreased during extension and lateral bending. During axial rotation intradiscal pressures at the superior segments slightly decreased while the pressure slightly increased at the inferior segment. Facet joint forces at all but one motion segment steadily increased with progression of degeneration in extension, lateral bending, and axial rotation; the force at the C4-C5 slightly decreased in early stages of degeneration during axial rotation.

Figure:



Caption: Developed FE models of the healthy and degenerated cervical spine. Boundary and loading conditions are represented for the healthy cervical spine

Conclusion: The results of this study showed that segmental motion and intradiscal pressure at the degenerated segment decreased with progression of degeneration, whereas the facet joint force increased. Segmental motions and facet joint forces at the adjacent segments increased with progression of degeneration, whereas intradiscal pressure slightly increased in flexion and slightly decreased in extension and lateral bending. These changes in spine biomechanics caused by intervertebral disc and facet joint degeneration would be a possible reason for accelerated disc degeneration at the healthy adjacent segments and worsening osteoarthritis at the degenerated segment. The results of this study could be used to understand the mechanism of injury caused by intervertebral disc and facet joint degeneration.

Table:

		C2-C3	C3-C4	C4-C5	C5-C6	C6-C7
Segmental rotation during flexion-extension (°)	Healthy	7.8	7.9	7.5	7.9	9.6
	Mild degeneration	7.9	7.9	7.6	7.6	9.7

AXIAL ROTATION IN THE LUMBAR SPINE AND ITS EFFECT ON ASSOCIATED NERVE TISSUE

Graham Mayberry [1,*] Janessa Drake [1]

[1]Kinesiology and Health Science, York University, Toronto, Canada

Introduction and Objectives: The lumbar spine has been characterized under a variety of different conditions, providing researchers with a strong understanding of its functional anatomy. The relationship between the intervertebral foramen (IVF) and the spinal nerve root (NR) that exits through it has not been quanitified, though it may play a significant role in how or whether individuals experience LBP (Lee et al, 2009). Nowicki et al (1996) conducted an invitro study using magnetic resonance imaging (MRI) to measure compression of the nerve root by ligamentum flavum or the intervertebral disc, while more recently Senoo et al (2014) used computerized tomography to quantify the heights and widths of the lumbar foramen invivo. These works did not quantify the IVF-SNR relationship in various postures invivo using MRI . The specific research goals of the current invivo study were to quantify the cross-sectional area (CSA) and volume of the IVF and NR in both neutral and axially-rotated positions in the lumbar spine.

Methods: Two healthy males (24.0 +/- 2.0) were recruited for this study with no history of LBP over the previous 12 months and successfully passed the MRI screening process. During the imaging session, the participants were asked to lie in a supine position with their shoulders strapped down while 3D MRI scans were acquired (Siemens MAGNETOM 3T Trio MRI scanner). The participants then moved to their maximal axially-rotated position (with their knees pointing to the left). Wedges were placed at the hips and between the knees, and straps were fastened around the shoulders, knees and hips to ensure they were comfortable and would not move during imaging. The lumbar spine was imaged, focusing on the levels of L4-L5, providing a complete functional spinal unit (FSU). The imaging protocol was T2SPC, with a slice thickness of 0.781mm, lasting six minutes per scan. The images were analyzed using OsiriX (© Pixmeo Sarl, V 5.0.1) and TurtleSeg (V 1.3.0.1777) for CSA and volume, respectively. The CSA for both the NR and IVF were calculated by averaging the seven smallest CSAs from the entire series of slices along an axis that was manipulated to run directly through the center of the IVF perpendicular to the saggital plane. The volume of both the IVF and NR was measured from the medial side to the lateral side of the pedicles of the FSU (see Figure 1).

Results: The right IVF and SNR of the L4-L5 FSU were quantified in both the supine (SUP) and axially-rotated (AR) positions in terms of the volume, CSA, and ratio of IVF to NR (see Table 1). The CSA of the IVF in Subject A increased from supine to axially-rotated while decreasing in the Subject B, however the CSA of the SNR decreased in both subjects. The IVF:NR ratio increased from supine to axial rotation for both subjects when using CSA analysis. When using the volumetric analysis, the SNR decreased for both subjects, while the IVF and IVF:NR ratio got larger for Subject A but got smaller for Subject B.

Figure:

Caption: Figure 1. Example of volumetric segmentation of the IVF (green) and SNR (purple).

Conclusion: Although the two subjects demonstrated different patterns in some aspects of this analysis, there were some important findings that could help direct future studies and improve our understanding of the body's response to various movements. We believe that the decrease in SNR cross-sectional area and volume when comparing a supine to an axially-rotated position is likely due to stretching and may be why individuals are susceptible to LBP if that position is maintained. Despite the consistency in the NR, the IVF was not consistent between subjects and we suspect it could be due to a pelvic tilt accompanying the axially rotated position, as participant's were instructed only to get comfortable in their maximal position. Anecdotally, in pre-trials where subjects were asked to remain in the supported-rotated position until comfortable, Subject A (increased IVF) time was much longer than Subject B (decreased IVF). In light of the opposite IVF size changes at the L4-L5 level, future research will examine more lumbar levels to see whether these differences hold along the spine. The findings of the current study are valuable, as no previous research has investigated this relationship invivo and in both neutral and deviated positions. If we are to understand the epidemic of LBP, a neurological understanding is critical.

Table:

			S 1	S 2	Ave
CSA (cm^2)	SUP	IVF	1.053	0.988	1.020
		NR	0.135	0.214	0.175

THE EFFECT OF THE PILATES PRACTICE ON YOUNG ADULTS´ POSTURE

Alessandra B. Porto [1,*] Túlio Moura [1] Celina Qurino [1] Victor Okazaki [1]

[1]CEFE, Londrina State University, Londrina, Brazil

Introduction and Objectives: The muscle and bone balance maintains a good posture that protects the body from damage and pain [1]. Some daily habits of bad posture can develop deformities [1]. On the other hand, the practice of physical exercises may help to prevent and treat some posture problems [2]. Pilates has shown to be efficient on the treatment of low back pain and some postural disorders [3].

Pilates has become a progressively popular method of exercise to achieve a better postural alignment [4,5]. Pilates exercises can be floor-based that uses the gravity to resist and assist the movement execution and can involve the use of specialized equipment [6]. This method can be also used in treatment of rehabilitation, emphasizing the core stability and posture [7].

Emery et al [3] studied the effect of the Pilates (using mat and equipment) and verified that 12-weeks of training was effective in posture. However, it is important to verify if those changes that happened with the Pilates method during all those decades still brings benefits to the practitioner´s posture and if the floor-based Pilates method, which is not an expensive method and can be instructed in any place without equipment, can improve postural disorders. Thus, the aim of this study was to verify the effect of the Pilates method on young adults´ posture.

Methods: The research was conducted in the Laboratory of Biomechanics at Londrina State University. Volunteered in the study 10 women, mean age of 40 years old (SD=12.8). They had their posture assessed before they started the Pilates classes and after 10 weeks of practice. The practice consisted on 50 minutes of mat Pilates, performed twice a week, for 10 weeks, totaling 20 sessions.

The 50 minutes Pilates´ session consisted in 10 minutes warm up, 30 minutes of Pilate´s exercises on the floor, using a mat and a professional Pilates´ ball, and 10 minutes of light exercises to finish the session. The Pilate´s exercises was medium and high intensity and varied between the sessions.

The posture assessment was realized by Photogrammetry, in which the spinal processes of the C7, T12 and L5 vertebras were identified by the palpation method [8] and external markers were attached on the skin with double-sided tape. After that, the participants positioned in orthostatic position, than 3 photos were taken in sagittal plane. The external markers were taken off and a marker made of half sphere of Styrofoam were placed in the same place as the other marker. Three more photos of the back were taken in frontal plane.

All the photos were unloaded into a computer and were analyzed in SAPO software. The software provided the thoracic angle formed by the C7 and T12 markers, the lumbar angle formed by T12 and L5 from the photos on sagittal plane. From the photos on frontal plane, the SAPO provided the angle between the C7-T12 and T12-L5, both in relation to a vertical line.

As the normality was assumed by the Shapiro Wilk´s test, the Student´s T test for paired measures was used to identify differences between the pre and post assessment. Statistical significance adopted was 5% (P<0.05).

Results: The analysis showed differences only for the C7-T12 assessment on frontal plane in pre and post evaluation (P=0.03) in which the mean of the angles in pre were greater (1.88^0, SD=0.96) than in the post assessment (1.05^0, SD=0.75). For the thoracic angle there was a tendency of decreasing the mean of the angles from the pre to the post assessment, but without statistical significance (P=0.083). The frontal plane analysis of the region T12-L5 showed no significant effect (Table 1).

The results of the present study corroborated with Emery´s [3] study that showed an improvement on posture with the Pilates after 12 weeks training. In the present study, only 10 weeks of floor-based Pilates training, was enough to show some modification on posture (thoracic region). Perhaps, a prolonged period of floor-based Pilates training would even maximize its effects on posture.

Conclusion: The Pilates practice used in the present study seems to influence subjects posture (thoracic portion of the spine mainly on frontal plane) and might help to correct the scoliosis problem. It was suggested for future studies a prolonged time of Pilates training in both technique and more participants performing the intervention.

Table:

	Pre	Post	P
Thoracic angles	39.84°(7.74)	38.54°(13.62)	0.083
Lumbar angles	32.39°(11.81)	28.98°(13.62)	0.130
C7-T12	1.88°(0.96)	1.05°(0.75)	0.037*
T12-C7	1.71°(1.68)	1.82°(0.94)	0.779

IN VITRO COUPLED MOTIONS IN THE ELDERLY HUMAN VERSUS THE YOUNG PORCINE SPINE IN CYCLIC AND CREEP LOADING

Idsart Kingma [1,*] Iris Busscher [2] Albert J. van der Veen [3] Gijsbertus J. Verkerke [4] Albert G. Veldhuizen [2] Jasper Homminga [4] Jaap H. van Dieën [1]

[1]Faculty of Human Movement Science, VU University Amsterdam, Amsterdam, [2]Department of Orthopedics, University Medical Center Groningen, Groningen, [3]Department of Physics and Medical Technology, VU University Medical Center, Amsterdam, [4]Department of Biomechanical Engineering, University of Twente, Enschede, Netherlands

Introduction and Objectives: When a spine segment is loaded about a single axis, this causes rotations about other axes as well. Such motions, which are often described as coupled motions, are partly induced by orientations of the facet joints, which vary along the spine. Furthermore, spinal asymmetry likely enhances coupled motions. This asymmetry may be larger in elderly and degenerated spines than in young spines. As young human spines are hard to retrieve, we used porcine spines as a proxy for young human spines, to compare with elderly human spines. We hypothesized that, compared to young porcine spines, human spines would show larger coupled motions, and that this difference would depend on spinal level and loading direction.

Methods: Six elderly human (55-84 years of age) and six young porcine fresh frozen cadaveric spines were dissected. Each spine was sectioned in high thoracic, mid thoracic, low thoracic and lumbar segments, consisting of 4 vertebrae each. The top and bottom vertebrae of each segment were embedded in neutral orientation in an alloy (Cerrolow-147) and positioned in a custom-made four-point bending device. After 1-hour preloading at 250 N compression, specimens were cyclically loaded (3 cycles, 0.5 degrees/sec) up to 4 Nm (human spines) or 2 Nm (porcine spines) in Flexion-Extension (FE), Lateral Bending (LB), and Axial Rotation (AR). Subsequently, spine segments were continuously loaded at half of these loads for 30 minutes in LB, AR, flexion and extension. Three-dimensional motions of the middle two vertebrae were recorded and decomposed into FE, LB and AR using Euler decomposition, starting with the loaded direction. Motions about the non-loaded (coupling) axes were expressed relative to motions about the loaded axes.

Results: In cyclic loading of human spines, relative coupled motions averaged over spines ranged from 11% (for FE coupling in LB loading of the lumbar segment) to 68% (for FE coupling in AR loading of the lumbar segment), and were up to 60% in FE loading. Averaged over spine sections, loading directions and coupling axes, relative coupled motions were larger in human than in porcine segments (27% vs 14%, $P<0.001$). In creep loading, relative coupled motions in human spine segments, ranged from 19% (for LB in extension loading of high thoracic spine sections), to 148% (for AR in extension loading of mid thoracic spine sections). The average was 46 % of the creep in the loaded direction, which was much larger ($P<0.001$) than for porcine spines (15%). In both creep loading and cyclic loading, differences with porcine spines depended on spine level and loading direction ($P<0.02$).

Conclusion: As anticipated, coupled motions varied highly with loading direction and with spine level. More importantly, coupled motions were about twice as high in elderly human spines compared to young porcine spines in cyclic loading, and these effects were even more pronounced in creep loading. Even in FE loading, large coupled motions were seen in

human spines. These findings suggest that asymmetry in stiffness and/or geometry contribute substantially to coupled motions in elderly human spines.

PO-0315

USE OF INERTIA SENSORS TO MEASURE THREE-DIMENSIONAL TRUNK MOMENT AND MOTION DURING WALKING

Jordan Berceville [1] Raymond Lee [2] Jin Luo [3,*]

[1]National Institutes of Applied Sciences (INSA), Strasbourg, France, [2]London South Bank University, [3]Department of Life Sciences, University of Roehampton, London, United Kingdom

Introduction and Objectives: Walking is a popular exercise to enhance musculoskeletal health and physical function in ageing population. To ensure that walking exercise can be conducted both effectively and safely, especially for people with osteoporosis and obesity, it is important to quantify the mechanical loading applied to the spine during walking. Current methods of measuring spinal loading have their limitations as they require the use of laboratory bound equipment such as force platform or video camera system [1,2]. The objective of this study was to develop a method that uses inertia sensors to measure trunk moment and motion during walking.

Methods: A biomechanical model of trunk consisting of three segments (head and trunk, left arm, and right arm) was created. Each segment was treated as rigid body. Head and trunk articulated with lower body at L5/S1 joint. Left and right arms articulated with trunk at left and right shoulder joints respectively. The dynamic equilibrium equations that described the moment about the L5/S1 joint were developed in sagittal, frontal, and transverse plane.

In order to obtain these moments, the 3-D orientation of each segment and the 3-D coordinates of its centre of mass (COM) at any time point during walking were determined by measurement and calculation. The 3-D orientation angles were measured by attaching four inertia sensors to the skin surface at locations corresponding to COM. The 3-D coordinates of COM were determined by the following method: first, a Fastrak system was used to digitize the 3-D coordinates of the four inertia sensors at time zero which were used as the stationary initial position of COM in the model. The 3-D coordinates at any following time points were then calculated through matrix transformation method by using 3-D orientation angles at that time point and 3-D coordinates at time zero [2]. All 3-D coordinates and moments were expressed in an anatomical reference system defined by ASIS and PSIS.

Ten adult male (Age: 45.5 ± 21.8 years) took part in the experiment. Their anthorpometric measurements were taken in order to estimate segment mass and moment of inertia. They were then asked to walk in a straight line with their normal walking speed for about 20 meters in a biomechanics lab. The walking trial was then repeated after 1-min rest. The data were analyzed by a customized MATLAB program to obtain 3-D trunk moment and motion. Maximum and minimum of trunk moment and motion during one full stride (from right heel contact to the subsequent right heel contact) were determined. Trunk moments were normalized to percentage of the product of body weight and height (joint moment/(body weight x height)) x100).

Results: As seen in table 1, trunk moment and motion obtained in the present study are in good agreement with a previous study [2] which used a bottom up rigid link segment analysis method.

Conclusion: The current study has successfully developed a method using inertia sensors to measure trunk moment and motion during walking. The strength of our method is that it can be easily implemented in the natural environment as it does not require laboratory bound equipment such as video camera system or force platform.

PO-0312

CHANGES IN THE STANDING LUMBAR SPINE AT ABOVE BODYWEIGHT LOADING

Gary Dougill [1,*]Neil Reeves [2]Christine Le Maitre [3]Glen Cooper [1]

[1]Engineering, [2]Healthcare Science, Manchester Metropolitan University, Manchester, [3]Biomedical Research Centre, Sheffield Hallam University, Sheffield, United Kingdom

Introduction and Objectives: Understanding the mechanical response of the spine and intervertebral disc to various loading situations is vital to predicting its behaviour, to verify computer models of the spine and to gaining insight in to how loading and spinal posture may cause or exacerbate injury.

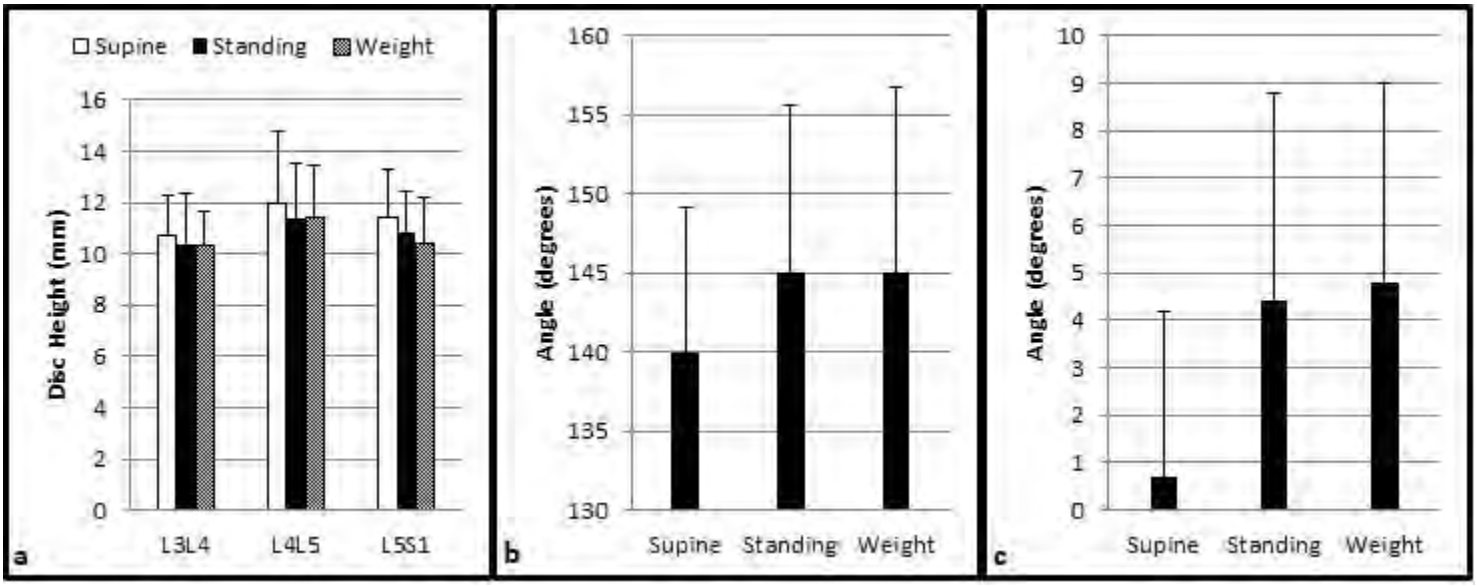
Studies of the lumbar spine and intervertebral disc under compression have typically been carried out in vitro; those which have used in vivo methods have mostly been conducted in the supine position at loading equal to or below static bodyweight. This study measures the lumbar spine response to above bodyweight loading in the standing position at loads equivalent to walking.

Methods: Sagittal plane magnetic resonance imaging scans of the spine were taken of nine asymptomatic male subjects (22-32 years of age, 167-195 cm, 66.3-93.2 kg) in the supine and standing positions with a third scan taken in the standing position with additional loading. Additional load was applied by having subjects hold two 6 kg kettlebells, one in each hand, enough to increase loading on the IVD to levels experienced during walking.

Disc heights were measured as the average of anterior and posterior distance between adjacent vertebrae in the mid-sagittal plane. Change in lordosis was measured in two ways; the relative angle between the lumbar spine and pelvis was measured as the posterior angle between L5 and S1 vertebrae whilst change in the upper lumbar spine was measured by the angle between the superior facet of L3 with the vertical plane.

Results: Increased axial loading resulted in reduced disc height and lumbar lordosis. Initial disc heights in the supine position for L3/L4, L4/L5 and L5/S1 were found to be 10.7(1.6), 12.0(2.8) and 11.4(1.9) mm respectively (Fig. 1a). These heights were reduced to 10.4(1.9), 11.4(2.1) and 10.8(1.6) mm in the standing position and 10.3(1.4), 11.4(2.0) and 10.4(1.8) mm with additional loading but these changes were not statistically significant ($P>0.05$). Lumbar angle in supine, standing and with additional loading was found to be 140(9), 145(11) and 145(12) degrees respectively (Fig. 1b) with L3 angled 0.7 (3.5), 4.4 (4.4) and 4.8 (4.2) degrees posteriorly from the horizontal in the three loading positions (Fig. 1c). In all cases disc height change was greater posteriorly as loading increased lumbar lordosis.

Figure:



Caption: Figure 1 - (a) Average IVD height of lower Lumbar discs in three loading positions. (b) Angle between Lumbar and Sacral spine in three loading positions. (c) Posterior tilt of L3 vertebrae in three loading positions.

Conclusion: Increased axial loading was found to progressively decrease intervertebral disc height; this change in height was not equal across the disc with reduced compression in the anterior region of the disc. Lordosis in the lumbar spine was found to increase with progressive loading; L5/S1 angle was greater in the standing position than supine whilst the superior facet of the L3 vertebrae was increasingly rotated posteriorly. Increased lumbar lordosis and compression in the posterior region of the disc with increased loading suggests that moderate axial loading in the upright position typical of that found during walking is not a risk factor in acute herniation of the intervertebral disc.

THE CHARACTERISTICS OF REGIONAL BONE QUALITY IN CERVICAL SPINE

Dai-Soon Kwak [1,*] In-Beom Kim [1] Moon-Kyu Kim [2]

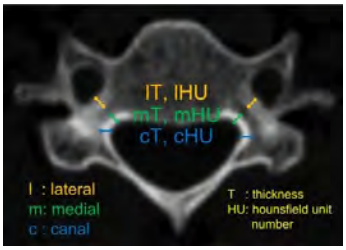
[1]Catholic Institute for Applied Anatomy, The Catholic University of Korea, Seoul, [2]Department of Neurosurgery, Gangneung Asan Hospital, Gangneung, Korea, Republic Of

Introduction and Objectives: Pedicle screw fixation has biomechanical advantages, but it was considered very risky due to neurovascular complications. Thus, a lot of anatomical studies were conducted. However, the anatomical study has still limitations about the individual shape difference of the vertebra. The freehand technique for cervical pedicle screw fixation was a method to complement these limitations. For performing a safety freehand technique, the strength or quality of bone at the cortical wall of the spinal canal (adjacent of the lateral mass), the medial and the lateral wall of pedicle have to be quantified to lead the probe. In this study, we evaluated the regional bone quality in cervical vertebra for safety guidance on freehand technique and related applications.

Methods: In this study, we used 99 patients' data (female: 51, male: 43, mean age: 64) of the cervical CT. The Hounsfield unit (HU) numbers and the thickness of cortical bone (T) in the vertebral canal (cHU/cT), the medial (mHU/mT) and lateral (lHU/lT) wall of pedicle were measured on the axial CT images in the middle of pedicle from C3 to C7 (fig.1). Then, we evaluated the difference in the thickness of cortical bone and the HU number among these regions.

Results: There was no statistical difference between the left and right side of cortical bone thickness and HU number. The largest cortical bone thickness was found in the vertebral canal (cT). And the smallest thickness was the lateral wall of the pedicle (lT). The mean thickness were 1.49±0.27 mm (cT), 1.40±0.22 mm (mT), and 1.02±0.25 mm (lT) ($p<0.01$). The HU No. was showed the highest value in the vertebral canal. The mean number of HU in vertebral canal, the medial wall and the lateral wall of pedicle 1083.43±202.15, 1031.13±206.89, and 688.65±233.41 respectively ($p<0.01$).

Figure:



Caption: Fig.1 Measurement parameters, thickness and mean Hounsfield unit numbers at each region

Conclusion: The cortical bone thickness in the vertebral canal and the medial wall of pedicle was thicker than the lateral wall. Moreover, the mean Hounsfield unit number in the vertebral canal wall and the medial wall of pedicle was larger than the lateral wall. Thus, the vertebral canal wall and the medial wall of pedicle were strong structure among these regions. And these structures could support the probe to make a safety trajectory for pedicle screw.

LIFTING AND BENDING DEMANDS OF THE VARIOUS TASKS PERFORMED BY DAYCARE WORKERS

Genevieve A. Dumas [1,*] Adam Labaj [1] Tara Diesbourg [2] Andre Plamondon [3] Hakim Mecheri [3]

[1]Mechanical and Materials Engineering, [2]SKHS, Queen's University, Kingston, [3]Ergonomie, IRSST, Montreal, Canada

Introduction and Objectives: Research from the 1990s identified that daycare workers are subjected to high postural and lifting demands, and made recommendations concerning furniture and work organisation [1], but few studies have quantified these demands with physical measurements. The objective of this study was to quantify bending and lifting demands on current daycare workers and identify the tasks for which these demands are the highest and should be first considered for improvement.

Methods: Caregivers from five daycares were recruited to participate in the study. They were recorded by video camera for ~ 3.3 hours in the morning of their shift. All children and objects (>1kg) lifted were weighed. Participants' trunk posture was monitored with a dosimeter designed at IRSST [2]; absolute trunk orientation with respect to the vertical and relative flexion-extension between T1 and S1 were continuously recorded.

Video recordings were observed to identify the main tasks performed by the workers. All lifts for which there was a good quality video image were analysed with 3D-SSPP and compression and shear at L5/SI determined. Posture was analysed using APDF and Exposure Variation Analysis (EVA) [3]. Summary scores along the flexion angle amplitude axis (FAA) and the flexion duration axis (FD) were computed to find the average position of the EVA distribution on each axis [4] and used as a measure of postural exposure.

Results: Of the 24 participants (23 females, 1 male; mass - 70.9±25.0 kg, height - 163±8cm), 7 worked with infants (0 - 1.5 yr), 7 with toddlers (1.5 - 2.5 yr), and 10 with pre-school children (2.5 - 4 yr). Eleven tasks were identified and their percentages of collection time computed (Fig. 1).

Workers lifted on average 501 kg during collection time with one lift every four minutes; 54% of the lifts involved children. Most of the weight was lifted during two tasks (Table 1): "**Preparation**" when workers get children (e.g. putting on snowsuits) and room ready for an activity (e.g. setting up for arts and crafts) and "**Changing diapers**" when they lift children to the changing table. The average weight lifted during these two tasks was 7.7 and 12.2 kg, and the average lifting frequency was 0.60 and 0.78 lifts per minute respectively. Compression(C) and shear(S) were highest in "Bathroom" (i.e. helping children in the bathroom) with C= 2858 N and S= 386N and putting children to sleep or "Nap", with C=2735 N and S=371 N, two tasks when few lifts were performed. Though these levels of exposure may not exceed recommended limits for lifting, it must be considered that other factors such as stability are not taken into account. The majority of lifts consisted in lifting a child who, unlike a box, may move in unpredictable ways.

For flexion angle from the vertical, APDF 90 reached 55º showing that workers experienced flexion angles greater than 55º more than 10% of collection time. For flexion between pelvis and upper trunk, APDF 90 was 50.5º. Based on the EVA summary score FAA, the most demanding tasks were "**Nap**" and "**Cleaning**" for absolute flexion and "**Activity**" (children performing an organised activity such as crafts), "**Playing**" and "**Nap**" for relative flexion. For these tasks, the summary score of FAA fell in the EVA class of 20º to 30º which is far from a safer erect posture (0-10 º). "**Activity**" and "**Nap**" were

also the tasks with the highest duration summary scores falling in EVA classes of 2 to 4 and 4 to 8 seconds respectively. During these tasks, the workers were bending over for substantial periods of time to either help the children with their activity (“Activity”) or pat their backs to induce them to sleep (“Nap”).

Figure:

Caption: Percentage of collection time spent in each task.

Conclusion: The results showed that the tasks **“Preparation”** and **“Changing diapers”** were the most demanding in terms of lifting. For trunk posture, “**Activity**” and “**Nap**” were the most demanding both in amplitude of flexion and in duration for holding postures, while **“Cleaning and “Playing”** were demanding in amplitude of absolute or relative trunk flexion. In questionnaire data also collected in this study, the highest ranked and scored tasks identified by the workers were: **Outdoor Preparation**, **Diaper Changing**, **Playing**, **Cleaning**, **Moving Furniture** and **Nap** which shows a good overlap with the tasks identified above for their high demands either in lifting or trunk posture. The results are limited by the small number of daycares considered.

Table:

TASKS	TOTAL WEIGHT (kg)	AVERAGE TOTAL NUMBER OF LIFTS/WORKER	AVERAGE FREQUENCY (#lift/min)
PREPARATION	186	24.1	0.60
CHANGING DIAPERS	182	14.4	0.78
PLAYING	75	6.0	0.45
SUPERVISION	68	6.8	0.24
OTHER	36	3.5	0.30
CARING	33	2.9	0.47
ACTIVITY	32	2.7	0.10
BATHROOM	29	2.3	0.17
CLEANING	27	4.4	0.23
FEEDING	20	2.2	0.10
NAP	17	1.4	0.31

EFFECTS OF HEEL INSERTS ON SPATIO-TEMPORAL LOCOMOTION PARAMETERS IN ATHLETES WITH AND WITHOUT LOW BACK PAIN

Sophie Gondry [1] Clara Leyh [1 2] Marcel Rooze [1 2] Veronique Feipel [1 2,*]

[1]Laboratory of Functional Anatomy, [2]Laboratory of Anatomy, Biomechanics and Organogenesis, Université Libre de Bruxelles, Brussels, Belgium

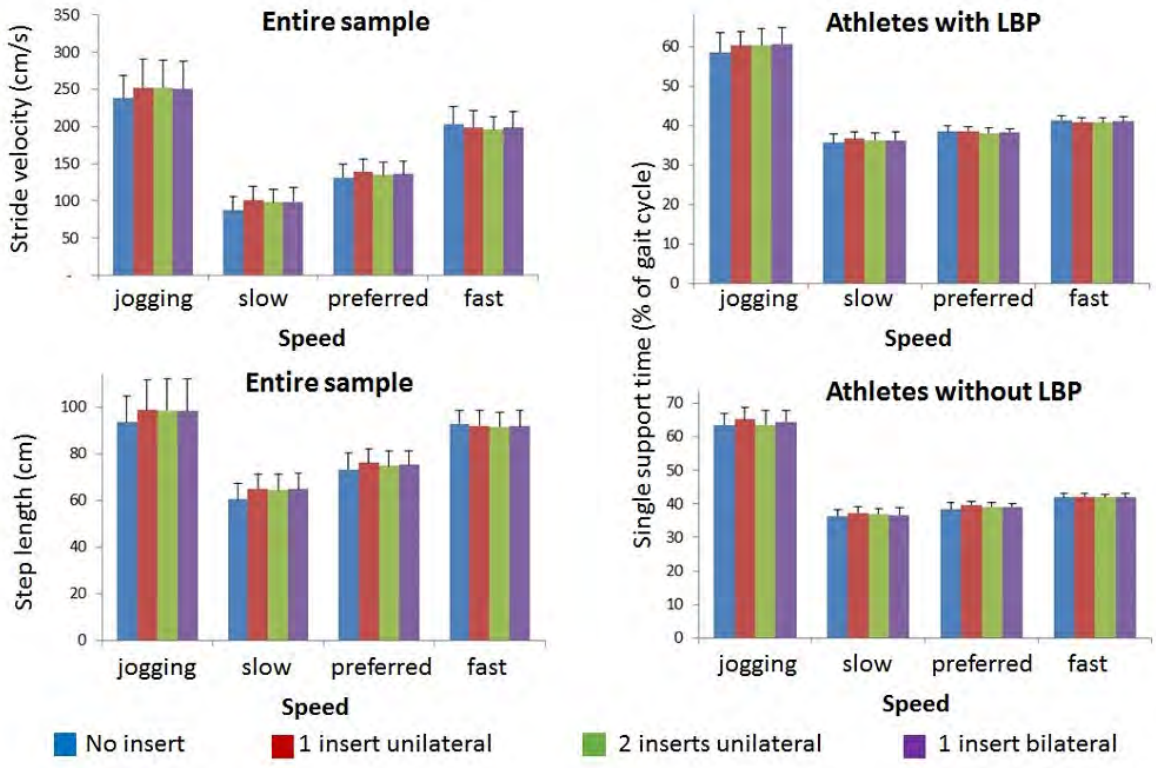
Introduction and Objectives: In the literature, the relationship between leg length discrepancy (LLD) and low back pain remains controversial and the existence of a causal relationship between LLD and low back pain remains unknown [5]. Nevertheless, LLD is frequently corrected by the use of heel inserts or other types of foot orthoses, and foot orthoses are frequently prescribed for the treatment of low back pain, including in athletes [5]. The mechanisms advanced to explain their potential efficacy in thre prevention or treatment of low back pain include a change in spinal muscle activity during jogging [2, 7] or shock absorbing properties [3]. The efficiency of foot orthoses in the treatment of low back pain remains, however, insufficiently explored [8]. The same review indicated that evidence does not support the efficacy of orthoses in the prevention of low back pain. A few studies [e.g. 4], probably of insufficient quality, showed however positive effects of heel inserts in patients with low back pain.

Our study was designed to compare the spatial and temporal parameters during gait and running, with and without heel inserts in healthy athletes and in athletes with low back pain.

Methods: 15 healthy athletes (6 females, mean age of 23 (SD 2) years) and 15 athletes with low back pain (11 females, mean age of 22 (SD 3) years) were invited to walk over the GAITRite instrumented walkway at various speeds (slow gait, preferred gait speed, fast gait, jogging) with different heel insert conditions (without heel inserts, wearing a unilateral 5 mm heel insert, wearing heel inserts bilaterally, wearing a double unilateral heel insert). Three trials were sampled for each condition. The order of heel insert conditions and locomotion speeds were randomized. The software associated with the GAITRite walkway computes spatial and temporal parameters from foot contacts on the embedded pressure sensors. It was shown to be reliable and valid [1, 6, 9]. Gait velocity, cadence, step length, cycle length, step width, step time, cycle time, stance time, swing time, and for gait trials single and double support times were extracted and averaged across trials. A repeated measures ANOVA was used to compare speeds and heel insert conditions (within-subject factors) and groups (between-subject factor).

Results: Wearing heel inserts, in subjects with low back pain and healthy subjects, significantly altered each parameter studied. An increased gait velocity, stride velocity, cadence, swing time, single support time and step length, as well as a reduced step time, cycle time, stance time, and double support time (for gait trials) were observed in the presence of heel inserts. For most of these variables, no significant group effect nor group x insert interaction was observed.

Figure:



Caption: Stride velocity, step length and single support time in both samples at different locomotion speeds.

Conclusion: In athletes, wearing heel inserts, whatever the configuration, changed the spatio-temporal locomotion parameters in the same direction as does an increase of gait speed. The results of the study do not allow to conclude that these heel changes related to heel inserts have an effect on reducing or preventing low back pain.

The hypotheses of a better restitution of elastic energy, better shock absorption [3] and an anterior imbalance modifying spinal muscle activities [2, 7], even if the heel inserts were used to correct leg length discrepancy are advanced and deserve further investigation, including the effect of wearing heel inserts in the longer term. The absence of familiarization with the wear of heel inserts might indeed be responsible for some of our observations.

WHOLE SPINE ALIGNMENT IN AUTOMOTIVE SEATED AND SUPINE POSTURES BY USING AN UPRIGHT OPEN MRI SYSTEM

Fusako Sato[*1], Mamiko Odani[2], Yui Endo[3], Mitsunori Tada[3], Yusuke Miyazaki[2], Taichi Nakajima[1], Koshiro Ono[4], Shigehiro Morikawa[5], Mats Svensson[6]

[1]Safety Research Division, Japan Automobile Research Institute, Ibaraki, [2]Tokyo Institute of Technology, [3]National Institute of Advanced Industrial Science and Technology, Tokyo, [4]Japan Automobile Research Institute, Ibaraki, [5]Shiga University of Medical Science, Shiga, Japan, [6]Chalmers University of Technology, Gothenburg, Sweden

Introduction and Objectives: Whiplash associated disorder (WAD) caused by rear-end car accidents is a worldwide problem. Many aspects of WAD are still unknown and further research to understand the injury causation and prevent WAD more effectively is needed. Human body finite element models have been used to study injury biomechanics in vehicle crashes. Those studies reported cervical spine kinematics which was considered to be related to WAD was affected by initial positions of thoracic-lumbar spine as well as cervical spine[1]. Therefore, the accurate knowledge of alignment of whole spine is important. However, alignment of whole spine in automotive seated posture has not been well reported in literature, particularly in females[2], generally due to availability of image data in supine[3].

The purpose of this study was to provide the alignment of whole spine in automotive seated posture by analyzing image data acquired with an upright open magnetic resonance imaging (MRI) system. Furthermore, this study showed the comparison of vertebral alignment between seated and supine postures in order to provide reference data to estimate spine alignment in seated posture by using conventional computed tomography (CT) or MRI data in supine.

Methods: Five female and two male subjects were scanned in seated and supine postures by an upright open MRI system (0.5T GE Signa SP MRI system) at Shiga University of Medical Science. Subjects were laid on their back on a horizontal table in supine. In seated posture, subjects were seated in a wooden rigid seat with a seatback angle of 20 ° from the vertical and seat pan angle of 10° from the horizontal. Then, the subjects were asked to face forward and relax. The specifications of the seat were defined based on the previous volunteer sled testing which simulated occupant kinematics during rear-end accidents [4]. The MRIs from the bottom of skull to coccygeal bone were acquired with 4 serial images changing the height of the seat. All subjects had no history of spine injury and provided informed consent.

MRI images were analyzed to extract the whole spine alignment. The spine curvature was determined by the vertebral angle relative to lower adjacent vertebra in the sagittal plane from C2 to sacrum in this study. The vertebral angles were defined as the angle of the mid-plane between superior and inferior endplates of each vertebral body. The angle measurements of sacrum were taken at its superior endplate.

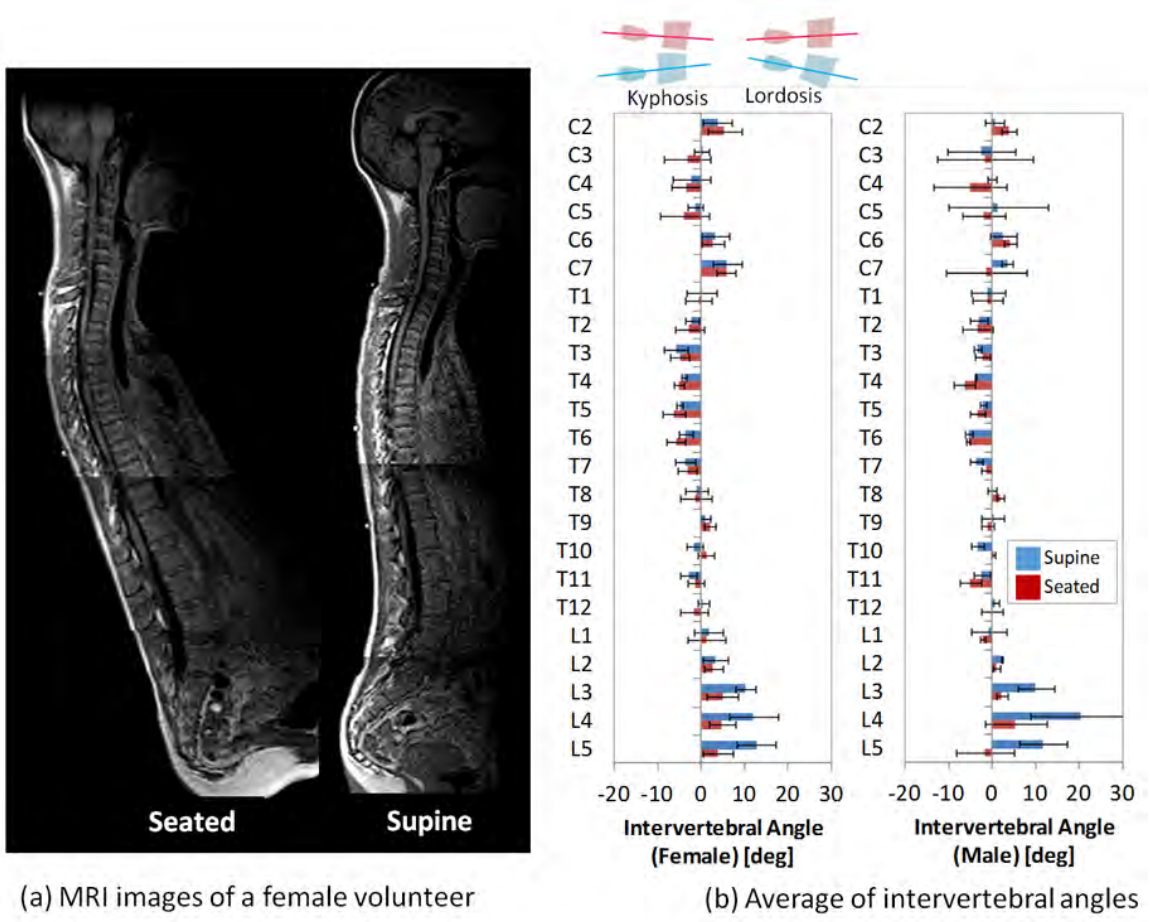
Results: From C2 to C5, intervertebral angles varied a great deal due to different types of cervical spine alignment. Four female and one male subjects had kyphosis and one female and male subjects lordosis.

C6 angle of all subjects and C7 angle of females exhibited lordosis. Then, thoracic spine from T1 to T7 showed kyphosis. Previous studies analyzed spine alignment in cervical and thoracic spine separately[5]. In addition, thoracic spine is commonly described in T4-T12 kyphosis angle[6]. Therefore, there was lack of information of connectivity between

cervical and thoracic spine[7]. However, results showed intervertebral angles from C7 to T3 were not so small as to be negligible and those values have a significant role in defining cervical spine orientation.

In the lumbar spine, intervertebral angles in supine were greater than that in seated posture. In this study, MRI scans of sagittal sections were obtained in 100mm width around spine, and the pelvic angle was extrapolated with the superior endplate angle of sacrum. Peleg[8] reported the angle between the line joining the anterosuperior iliac spine and the anterosuprtior edge of the symphisis pubis and the line along the sacrum superior endplate was 48.5±10.2°. The superior endplate of sacrum in seated posture was inclined at 1.6° for females and 9.3° for males from the horizontal. Therefore, the angle of line joining the anterosuperior iliac spine and the anterosuperior edge of the symphisis pubis in seated posture of this study was estimated at approximately 50.1° for females and 57.8° for malets from horizontal plane.

Figure:



(a) MRI images of a female volunteer

(b) Average of intervertebral angles

Caption: Fig. 1 MRI images and average intervertebral angles relative to each lower adjacent vertebra in seated and supine postures.

Conclusion: This study showed the whole spine alignment in seated posture by using an upright open MRI system which could take a scan without the risk of ionizing radiation. Results provided useful information to determine the whole spine alignment in seated posture. This will enable a more accurate starting posture and result in improved computer simulations of vertebral kinematics to investigate neck injury mechanisms.

PO-0322

EFFECTS OF THE SWIMMING PRACTICE ON SCAPULAR KINEMATICS IN CHILDREN AND ADOLESCENTS

Fernanda A. P. Habechian [1,*] Ana Leticia Lozana [1] Elisa Pires [1] Livia Pogetti [1] Paula Camargo [1]

[1]Physiotherapy, Federal University of São Carlos, Piracicaba, Brazil

Introduction and Objectives: Swimming is among the most popular sports worldwide. Ninety percent of the propulsive force is performed by the upper limb, requiring a great demand of the shoulder complex [1]. Adult elite swimmers are used to practice all week an average of 10,000 to 14,000 meters per day, which causes an overuse in the shoulder complex leading to shoulder pain and injuries [2]. In the current literature on this topic, most of the studies were conducted with adult swimmers. However, the number of children and adolescents participants in youth sports has increased as well as the injuries in their shoulder complex [3]. A better comprehension of the biomechanical aspects of the shoulder complex afforded by the swimming in this young population is warranted. Thus, the objective of this study was to evaluate the effects of the swimming practice on the 3-dimensional scapular kinematics in children and adolescents.

Methods: Twenty-eight male children/adolescents were evaluated and divided in 2 groups: 14 swimmers competitors (12.00 ± 1.95 years) and 14 non-swimmers (12.84 ± 1.35 years). All participants had no history of shoulder/cervical dysfunction and at least 150° of arm elevation. The swimmers had to practice the sport for a minimum of 1 year, at least 3 times per week and to participate in professional level competitions. The non-swimmers could not be involved to the practice of other sports involving the upper limb. Scapular kinematics was assessed with the electromagnetic tracking device Flock of Birds® integrated with the MotionMonitor™ software. Local coordinate systems were established using the digitized landmarks following the International Society of Biomechanics recommended protocol [4]. The dominant arm was evaluated and the individuals had to maintain light fingertip contact with a flat planar surface to keep positioning of the arm in the scapular plane. Three repetitions were performed of elevation of the arm. Scapular kinematics was analyzed at 30°, 60°, 90° and 120°. The data were averaged over the 3 repetitions. Shapiro-Wilk test was used to check the normality. A 2-way mixed model analysis of variance (ANOVA) was used for the 3 scapular rotations, in separate, considering humeral angle (30°, 60°, 90° and 120°) as within factor and group (swimmers and non-swimmers) as between factor. The Bonferroni test for post hoc analysis was used when necessary. A $p < 0.05$ was considered significant.

Results: Both groups had same pattern of scapular movement: increase internal rotation and upward rotation, and progression from anterior to posterior tilt during arm elevation. A 2-factor interaction was found where swimmers showed more internal rotation ($p<0.05$) at 90° and 120° of arm elevation compared to non-swimmers (mean difference: 6.34° and 8.28°, respectively). The non-swimmers presented slight external rotation at the end range of arm elevation while internal rotation continued until the end of elevation in the swimmers. It is important to remember that one of the most important modality of swimming is the crawl, and during this modality the internal rotation of the humerus is essential and probably the scapular internal rotation is needed as well [5]. For scapular upward rotation no differences were found ($p>0.05$) between groups. With regards to the scapular tilt, the swimmers had more posterior tilt at all angles of arm elevation (average mean difference: 5.9°). The literature has already showed that the serratus anterior is one of the most active muscle during the swimming in adults and it is also known that this is the only scapulothoracic muscle with the

capability to both upwardly rotate and posteriorly tilt the scapula on the thorax making its contribution to normal scapular kinematics very significant [2]. Its line of action will directly approximate the scapula to the thorax, which can serve as a stable base, which is extremely necessary during the swimming strokes.

Conclusion: The scapular kinematics pattern was similar between the groups, however the swimming practice seems to affect it. Swimmers have higher internal rotation at the end range of the arm elevation compared to non-swimmers and a higher posterior tilt at all angles of arm elevation. A more comprehensive understanding of scapular kinematics in the young population of swimmers can help in the development of appropriate evaluation, treatment and preventive protocols focused for children and adolescents swimmers.

PO-0323

EFFECTS OF DIFFERENT KNEE JOINT TAPING TYPE DURING A JUMP-STOP TASK

Po-Han Chang [1,*] Chen-Fu Huang [1] Tzu-Lin Wong [1] Min-Hao Hung [1]

[1] Physical Education, National Taiwan Normal University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Sport taping was used to prevent injure [1, 2], and it was popular on today's sport fields. Many sports had some common movements like jump-stop. This movement had to decrease speed quickly and maintain balance that make follow-up movement more easily and stability [3]. But jump-stop movement may increase the loading rate of anterior cruciate ligament (ACL) [4, 5, 6]. The purpose of this study was to investigate the effects of stability by using different types of taping on knee joint during a jump-stop task.

Methods: Eight healthy males (aged = 19.5 ± 1.2 year, height = 174.3 ± 5.9 cm, weight = 65.9 ± 4.2 kg) participated in this study. All the participants performed a jump-stop task under three knee taping conditions (traditional taping (TT), Kinesio taping (KT) and non-taping (NT)). A high speed camera (Mega Speed 30 Ks, 100Hz), two AMTI force plates (1000Hz) and four Biovision electromyography (EMG, 1000Hz) systems were used synchronously to collect kinematic, kinetic and EMG data during the landing phase. The Kwon3D and DASYLab 6.0 software were used for further analyses of the data. One-way repeated measures ANOVA and Scheffe methods was performed to compare the parameters among three conditions (a=.05).

Results: The results indicated that lower peak anterior-posterior ground reaction force (A-P GRF) and shorter displacement of anterior-posterior center of pressure were observed under the TT and KT conditions than the NT condition. A smaller average loading rate was reported with the KT compared to the NT. Regarding kinematic parameters, an increased knee flexion angle at peak impact was observed under the TT and KT conditions than the NT condition. A larger knee flexion ROM angle was reported under the KT compared to the NT. Furthermore, smaller mean EMG amplitudes were found in the rectus femoris and gastrocnemius muscles under the TT and KT conditions.

Conclusion: The study concluded that the traditional and Kinesio taping techniques effectively increases the stability by giving a strong support and limiting the forward displacement of the anterior cruciate ligament at a jump-stop task. The Kinesio taping is also beneficial to increase the range of motion of knee joint.

Table:

	NT (1)	TT (2)	KT (3)	F	Post hoc

PO-0324

VARIABILITY IN JOINT DYNAMICS IN CHILDREN AND ADULTS DURING COUNTERMOVEMENT JUMPS

Peter C. Raffalt [1,*] Tine Alkjær [1] Erik Simonsen [1]

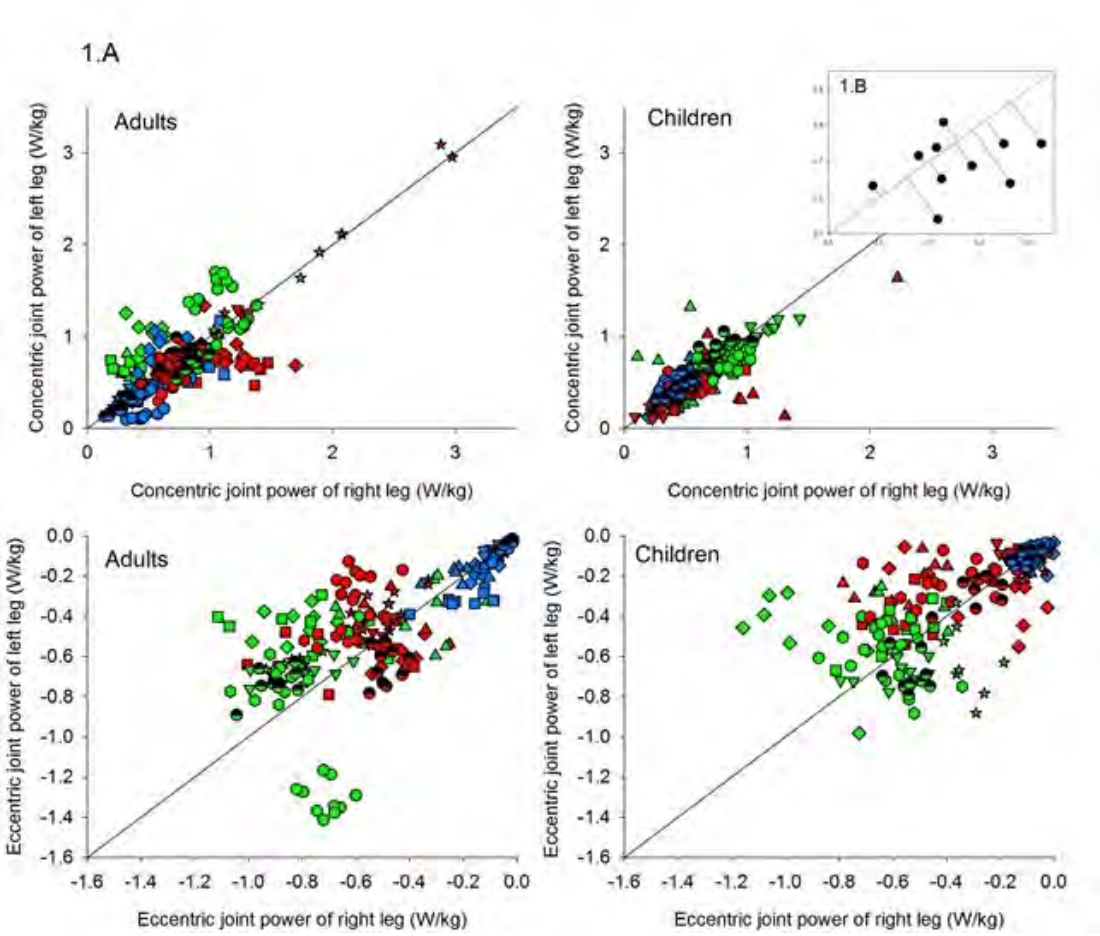
[1]Department of Neuroscience and Pharmacology, University of Copenhagen, Copenhagen, Denmark

Introduction and Objectives: Variability in inter-limb (between limbs) and intra-limb (within limbs) joint dynamics during whole body movements like vertical jumps can be used to evaluate both the limb-synchronization and consistency of movement pattern. It has recently been observed that the amount of variability in vertical ground reaction force during countermovement jump without arm swing does not differ between girls and adult women [1]. However, it is unknown if the coordination with respect to variability in limb-synchronization and movement pattern differs between children and adults. The purpose of the present study was to estimate the amount of variability in inter- and intra-limb synchrony of joint dynamics during countermovement jump in children and adults. We anticipate, that the adults show less variability in both inter- and intra-limb joint dynamics compared to children.

Methods: Nine boys (mean ± SD age: 11.8 ± 1.7 years, height: 157.1 ± 14.1 cm and mass: 41.7 ± 12.8 kg) and eight adults (25.6 ± 3.7 years, 181.7 ± 6.6 cm, 77.4 ± 11.0 kg) completed 9 consecutive maximal countermovement jumps without arm swing. Three-dimensional lower limb kinematics and ground reaction force from each foot were recorded. Inverse dynamics were used to calculate concentric and eccentric sagittal hip, knee and ankle joint power. Joint power was normalized to body mass. Right leg joint power from each jump of each subject was plotted against left leg joint power (figure 1A and 1B). Based on this plot three variables for each joint on both legs of each subject were calculated: 1) the average perpendicular distance from the coordinates from each joint to the line of identity as a measure of inter-leg joint power synchrony, 2) coefficient of variation (CV1) of the perpendicular distance from the coordinates from each joint to the line of identity as a measure of variability of inter-limb synchronization and 3) coefficient of variation (CV2) of the distances between the origin and the projection of each point on the line of identity as a measure of variability in intra-limb joint power generation. In addition, the relative variability of each joint contributing to the total power generated was calculated.

Results: No group differences were observed in inter-leg joint power synchrony or variability of inter-limb synchronization. The children had a significant higher variability in intra-limb eccentric and concentric power generation for the hip joint ($p < 0.05$) but not for the knee and ankle joint. This was confirmed by a higher variability in relative joint contribution of concentric power (table 1).

Figure:



Caption: Figure 1A: Concentric (top graph) and eccentric (bottom graph) joint power of right leg plotted against concentric joint power left leg (top graphs) for adults (left side) and children (right side). Each symbol represents a jump and each symbol type represents each subject. Red symbols are hip joint power, green symbols are knee joint power and blue symbols are ankle joint power. 1B: CV1 is calculated as the coefficient of variation of the perpendicular distances between each point and line of identity. CV2 is calculated as the coefficient of variation of the distances between the origin and the projection of each point on the line of identity.

Conclusion: The present study shows that children are capable of performing maximal countermovement jumps with the same level of joint power synchronization as adults [2]. However, children have a less consistent hip power generation compared to the adults. The present study supports previous studies, that have observed adult-like movement pattern in children during vertical jumps [1,2]. Based on the results presented in figure 1, it is clear that large individual differences exist in the variability of power contribution. This suggests that some individuals accomplish the movement according to a variety of different solutions while other individuals utilize a more consistent movement pattern.

Table:

Adult subject number	CV right hip	CV right knee	CV right ankle	CV left hip	CV left knee	CV left ankle
1	7.3	25.4	12.7	13.2	10.4	14.5

HIP, TRUNK AND SHOULDER STRENGTH IN THROWING ATHLETES WITH AND WITHOUT SHOULDER PAIN

Lívia S. Pogetti [1,*] Theresa Nakagawa [1] Elisa Pires [1] Paula Camargo [1]

[1] Physical Therapy, Federal University of São Carlos, São Carlos, Brazil

Introduction and Objectives: The dynamics involved in the throwing motion can be best understood by adopting the concept of force development through sequential segments of the kinetic chain. The kinetic chain is a coordinated sequence of activation, mobilization and stabilization of body segments, which places the distal segment in a great position, speed and time to produce the desired task.The majority of force required to propel the ball forward is developed in the hips and trunk. This force is sequentially transferred through the trunk, to the scapulohumeral complex to be transferred to the arm. Any change in a segment of the kinetic chain can increase the stress on the distal segments resulting in soreness or anatomic lesion. Thus, the objective of this study was to evaluate the muscle performance of the hip, trunk and shoulder of throwing athletes with and without shoulder pain.

Methods: Eight throwing athletes without shoulder pain (1 female and 7 males; 20.62±2.13 years; 84.87±18.69 kg; 177.25±7.28 cm) and 5 with shoulder pain (4 females and 1 male, 21.20±1.92 years; 59.8±8.64 kg; 161.6±8.82 cm) participated in this study. All of them were athletes in the college level of handball (n=8), baseball (n=2) and softball (n=2) modalities. Isokinetic concentric peak torque of the extensor muscles of the hip was measured at 60°/s for the impulsion leg; which is the ipsilateral leg to the throwing arm. The average of 5 repetitions was used to determine the peak torque. The trunk flexor muscle strength was measured in the supine position with a hand dynamometer. The average of 3 maximum voluntary isometric contraction repetitions was used for analysis. Isokinetic concentric peak torqueof the dominant arm was also analyzed by the average of 5 repetitions during internal and external rotation of the shoulder at 90º/s and 180º/s.The Student t-test for independent samples was used for group comparisons. An alfa level was set at .05.

Results: The group with shoulder pain showed lower isometric trunk flexor strength (pain group, 1.34±0.34N/kg; no pain group, 1.97±0.50N/kg; P=0.03); lower peak torque during external rotation at 90°/s (pain group,0.51±0.10 Nm/kg·m; no pain group, 1.01±0.21Nm/kg·m; P=0.03) and internal rotation at 90º/s (pain group, 0.63±0.10 Nm/kg·m; no pain group 0.93±0.29Nm/kg·m; P=0.03) when compared to the group with no shoulder pain. No significant differences were found between groups during external rotation at 180º/s (pain group, 0.56±0.14 Nm/kg·m; no pain group 1.02±0.20 Nm/kg·m; P=0.10), internal rotation at 180º/s (pain group, 0.64±0.15 Nm/kg·m; no pain group0.89±0.27 Nm/kg·m; P=0.07) and for the hip extension peak torque at 60°/s (pain group, 3.79±1.89Nm/kg·m; no pain group, 3.50±1.38 Nm/kg·m; P=0.77). The shoulder pain did not affect the ability to reach high velocity, possibly because all athletes continued with their regular routine of training, despite the pain. Considering the concept of integrated kinetic chain, the shoulder is the receiver and transmitter of the forces generated in the trunk, pelvis and hip. Therefore, the current results suggests that the appropriate function of the shoulder in throwing athletes with shoulder pain is impaired being potentially influenced by the weakness of the trunk flexors. These results provide a better understanding of possible changes in the segments of the kinetic chain

and can help the development of most appropriate and comprehensive protocols for assessment, treatment and prevention of injuries in this population.

Conclusion: The throwing athletes with shoulder pain showed lower trunk and shoulder strength compared with athletes without pain. Strengthening of the shoulder and trunk should be considered in the rehabilitation of these athletes.

THE KINETIC CHAIN ANALYSIS IN DIFFERENT LEVELS OF SOCCER PLAYERS DURING INSTEP KICK

Yo Chen [1,*]Wu-Yeh Chang [2]Yao-Ting Chang [1]Jia-Hao Chang [1]

[1]Department of Physical Education, National Taiwan Normal University, [2]Department of Ball Sports, University of Taipei, Taipei, Taiwan, Republic of China

Introduction and Objectives: Kicking is a natural fluid motion and a fundamental activity in soccer[1]. Elite players have a better kicking skill than general players. The ratio of ball-foot velocity and the kinetic chain have been used to understand the efficiency in soccer kicking. The purpose of this study was to improve the kicking skill in general players, thus we compared the kicking kinematics and measured the kinetics chain between elite and general soccer players.

Methods: Fourteen Taiwanese soccer players were recruited as participants in this study (elite group, EG: N= 7, Aged: 20.2 ± 1.0, Height: 173.3 ± 5.9 cm, Mass: 71.5 ± 15.7 kg; general group, GG: N= 7, Aged: 24.6 ± 2.4, Height: 169.1 ± 5.8 cm, Mass: 64.1 ± 8.9 kg). A VICON motion capture system (sampling rate at 200 Hz) was used to capture the kicking motions, and the plug-in-gait marker set was use to build full-body model. A radar gun was used to measure the peak ball velocity. Participants were asked to kick a ball three times in instep kick, and the kicking data with the fastest ball velocity was selected to analyse. The Visual3D was used to calculate the kicking kinematics. The ratio of ball-foot peak liner velocity was used to understand weather the ball was kicked on the centre of a ball. The measurements of foot peak liner velocity in back swing and forward swing, and the duration of kinetics chain transmit in segments were used to understand the kicking strategy between different levels of soccer players. The paired t-test ($\alpha = .05$) was applied to assess significant difference in this study.

Results: The greater ball velocity (EG: 27.4 ± 0.7 m/s; GG: 20.9 ± 1.0 m/s) and ball-foot ratio was found in elite grope (EG: 1.7 ± 0.1; GG: 1.4 ± 0.1). No differences were found in foot peak liner velocities. In back swing, the foot velocity was 7.20 ± 0.77 in EG and 7.28 ± 0.51 in GG. In forward swing, the foot velocity was 16.45 ± 1.69 in EG and 15.06 ± 0.92 in GG. The total time of kicking (from back swing to ball contact) was averaged 0.25 s in both group, and no differences were found in kinetic chain. It was 0.043 ± 0.012 s in EG and 0.038 ± 0.012 s in GG from the peak velocity of foot back swing to the peak velocity of thigh forward swing. Also, the similar duration was found from the peak velocity of thigh to the peak velocity of shank, it was 0.043 ± 0.010 s in EG and 0.038 ± 0.013 s in GG. From peak velocity of shank to peak velocity of foot it was 0.023 ± 0.008 s in EG and 0.016 ± 0.011 s in GG.

Conclusion: Elite and general players had similar characteristic of kinetic chain. According to the ball-foot ratio, elite players can kick a ball in the right position. To have a higher ball velocity, general players should improve their accuracy in ball-foot contact position.

PO-0327

BILATERAL DIFFERENCE IN TRUNK MUSCLE VOLUME IN MALE COLLEGIATE GOLF PLAYERS

Youka Izumoto [1,*] Michio Wachi [1] Tadashi Suga [1] Toshiyuki Kurihara [1] Tadao Isaka [1]

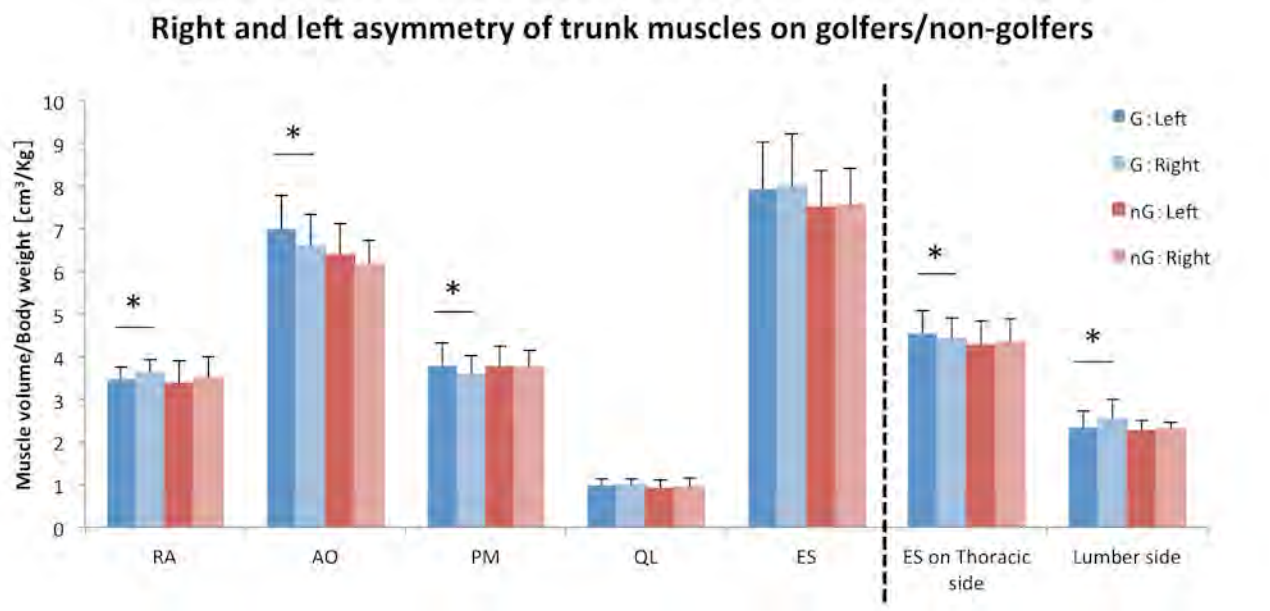
[1] Sport and Health Science, Ritsumeikan University, Kusatsu, Japan

Introduction and Objectives: Asymmetric activation of the bilateral trunk muscles is essential for effective golf swing (Marta et al., 2012). Such asymmetric activations were seen in the erector spinae and abdominal oblique (Watkins et al., 1996), muscles responsible for trunk twist and lateral bending. Therefore, recurrent golf swing practices could cause asymmetric hypertrophy on these trunk muscles. The purpose of this study was to investigate the degree of asymmetric hypertrophy on trunk muscles by measuring the muscle volume between left and right sides in male collegiate golf players.

Methods: Ten male right-handed collegiate golf players (golf players: age 20.5 ± 1.0 yrs, height 171.9 ± 5.7 cm, weight 64.8 ± 5.0 kg) and nine physically active right-handed college students who had never played golf (non-golf players: age 22.3 ± 0.6 yrs, height 172.0 ± 5.0 cm, weight 66.8 ± 9.3 kg) participated in this study. Golf players had at least 4 years of experience in golf practice (8.8 ± 3.6 yrs). They regularly practiced at a golf training center (1.5 ± 0.4 hours for 3.9 ± 1.4 days / week), and played on a golf course (1.4 ± 0.7 rounds / week). The MR images were obtained with a 1.5-T magnetic resonance system (Signa HDxt; GE Medical Systems) while the subjects lying supine. Serial transverse MR images (1cm slice thickness) were obtained from the intervertebral space between the 4th and 5th thoracic vertebrae to the lower part of the sacrum. With the use of the intervertebral space between the 5^{th} lumbar and 1^{st} sacral vertebrae as the point of origin (0cm), the images of every 3 cm slice to the head (e.g. +3cm, +6cm…) and to the caudal regions (e.g. -3cm, -6cm…) were used to estimate muscle volume. Cross-sectional area of the trunk muscles (rectus abdominis, abdominal obliques, psoas major, quadratus lumborum, and erecror spinae) was determined (SliceOmatic ver.5.0 rev-4b2, Tomovision), and was then multiplied by 3cm to estimate muscle volume for each slice. As for the erector spinae, the muscle volume was divided into the lumbar (levels from 0cm to 18cm) and thoracic regions (levels higher than +18cm). The degree of bilateral asymmetry for each trunk muscles was calculated as the left to right volume ratio (= (right - left) / right * 100).

Results: There were no significant differences in the volume of each muscle between the golf players and non-golf players. In the golf players, the muscle volume on the right side was significantly larger than that on the left side for the rectus abdominis, while the muscle volume was significantly larger on the left side for the abdominal oblique and psoas major. Moreover, although no significant difference was observed in the total muscle volume for the erector spinae, the opposite side was larger in muscle volume between the thoracic and lumbar regions for the golf players: the right side was significantly larger than the left side in the thoracic region, whereas the left side was larger in the lumbar region. For the non-golf players, there was no such bilateral difference between the thoracic and lumber regions within erector spinae.

Figure:



Caption: * < 0.05. G : golf player, nG : non-golf player, RA : rectus abdominis, AO : abdominal obliques, PM : psoas major, QL : quadratus lumborum, ES : erecror spinae. Thoracic side is 0cm~+18cm of ES, Lumber side is +18cm~ of ES.

Conclusion: The male collegiate golf players demonstrated bilateral difference in muscle volume in the rectus abdominis, abdominal oblique, and thoracic and lumber regions of the erector spinae. Right-handed golf players are known to twist their trunk to the left and bend it to the right (Okuda et al., 2010; Sugaya et al., 1996). Larger muscle volume obtained in the left abdominal oblique and right erector spinae seem to result from such trunk motion. These findings suggested that recurrent golf practice could cause asymmetric hypertrophy in the left abdominal oblique and right erector spinae for right-handed golfers. Such asymmetric muscle hypertrophy in the bilateral trunk muscles would also be seen in the other sports that require asymmetric trunk motion, such as cricket, tennis, and field throwing events.

PO-0328

STUDY ON THE DOUBLE ROUNDHOUSE KICK FOCUSED ON THE BRINGING DOWN LEG AFTER THE FIRST IMPACT

Madoka KINOSHITA [1,*] Norihisa FUJII [2]

[1]Graduate School of Comprehensive Human Sciences, [2]Health and Sport Sciences, University of TSUKUBA, Tsukuba, Japan

Introduction and Objectives: Taekwondo is an Olympic event characterized by a diverse array of kicking techniques. Because the rules were changed recently, accurate and continuous kicks to the opponent are required instead of kicks with strong impact forces to win the competition. According to previous studies (Falco et al., 2012; Kim et al., 2011), roundhouse kick (RHK) was one of the most critical and basic kicks. Some researches were focused on a single RHK. There are few researches about a multiple RHK. As mentioned above, multiple RHK is required to win the game. Our previous studies about double RHK (Kinoshita et al., 2014) showed that the trial time of the phase from the 1st impact to the 2nd toe off the floor (DOWN phase) was accounted as 30% of total trial time (from start to 2nd impact). Technique of DOWN phase had a relation to shortening the total trial time, and to the fast and quick kicking in 2nd kicking phase because of long time and the characteristics as preparatory phase. They also showed that there were some types of way to bring down the kicking leg based on the path of knee (I-type and S-type, Figure 1 b)).

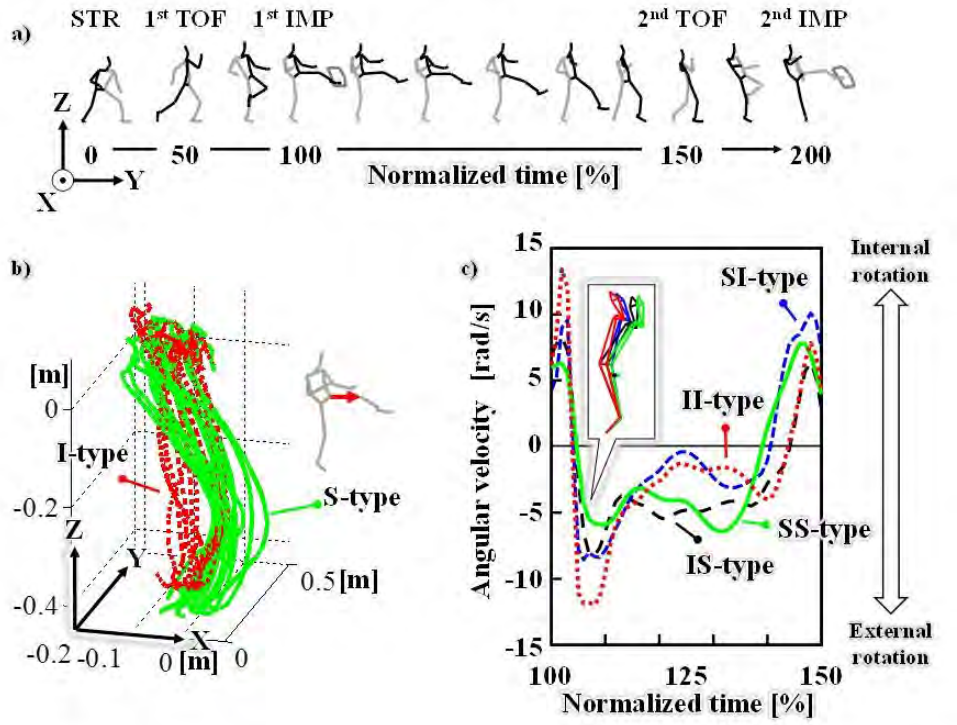
The purpose of this study was to analyze the double RHK in the phase from 1st impact to the 2nd toe off in order to get the some knowledge of mechanisms that gives a reason for the type of way, and to find the way to bring down the leg suitable for taekwondo.

Methods: Ten male Japanese Taekwondo athletes (with age: 21.4±3.2 [yr], height: 1.72±0.04 [m], body mass: 66.7±12.7 [kg], and experience: 6.5±5.9 [yr]) participated in this study after informed consent. The participants had the diverse skill levels (national game level - not in particular). Experiment trial consisted of double RHK to a target with preferred leg and non-preferred leg alternately. The 3D coordinates of reflective markers on the body and the target were captured by a motion capture system (Vicon MX+, 250 Hz), and filtered the captured data with a Butterworth digital filter (12.5-25.0 Hz) (Wells et al., 1980). The ground reaction forces were obtained for both legs by force platforms (Kistler, 1000 Hz). The total analysis trial was 28 trials (0-4 trials per subject). To normalize a kicking motion, the trial motion was divided at 0% (start to kick, STR), 50% (1st toe off the floor, 1st TOF), 100% (1st impact, 1st IMP), 150% (2nd toe off the floor, 2nd TOF), and 200% (2nd impact, 2nd IMP) as figure 1 a). The analysed phase was from 100% (1st IMP) to 150% (2nd TOF) termed “DOWN phase”. Both averaged I-type and S-type motions about two segments (pelvis-thigh and shank-foot in bringing down leg) were reconstructed for inverse and forward dynamics simulation based on hip joint coordinate value in support leg. Four type (II-type, IS-type, SI-type, and SS-type) of motion data were produced by reconstructed data to investigate the reason why the type of motion were divided.

Results: Figure 1 c) showed that the angular velocities of hip internal-external rotation in the bringing down leg. The magnitudes of external angular velocities were different among 4 types about 110% time. After that, the angular velocities branched off into two patterns (II-type, SI-type and SS-type, IS-type).

In this report, there is no figure on the position of each segments, angular velocity of knee joint, torque, and etc. In view of the kinematics results, both IS-type and SI-type (combined type) were considered as a feasible motion. Among all types, motions of hip external rotation and knee flexion-extension had the relations to the shank motion. On the other hand, for the kinetics results, the combined types showed that larger constrained torque of knee joint was required to perform. Original types (II-type, SS-type) showed almost same magnitude of torque nevertheless their motions were quite different.

Figure:



Caption: Figure 1 a) Motion of double roundhouse kick. b) Locus of the knee joint based on hip joint. c) Angular velocity of internal-external rotation.

Conclusion: This study provided a new insight into the mechanism of the motion about bringing down leg in DOWN phase. GOOD athletes bring down their leg by the same way, that is the same joint torque. However, the type of way to bring down their leg with the movement of hip external rotation was settled by the knee position at the 1st impact. It is our view that the coaches should pay more attention to the DOWN phase in which there are many suitable types of way for bringing down the leg.

PO-0329

INFLUENCE OF UNILATERAL AND BILATERAL ANKLE BRACING ON JOINT KINEMATICS OF THE BRACED AND NON-BRACED ANKLE JOINT.

Andrew Greenhalgh [1,*]Victor Lonchuk [1]Amey Kolekar [1]Jonathan Sinclair [2]

[1]London sports Institute, Middlesex University, London, [2]University of Central Lancashire, Preston, United Kingdom

Introduction and Objectives: In many sports ankle sprain is the most common injury reported (Fong et al., 2007). During jogging, significant inversion and external rotation have been associated with Chronic ankle instability (Drewes et al., 2009). Ankle bracing is widely used in many sports as a way of reducing the prevalence of such injuries (Dizon and Reyes, 2010; McGuine et al., 2012). Whilst the effects of bracing on an ankle joint appear to have a body of evidence supporting a change in movement, little is known on the effects of a braced foot on the opposite ankle movement. Due to changes in movements on one side of the body there may well be an effect on the other.

There is a paucity of research comparing the same bracing system used in a bilateral or unilateral approach. Therefore the aim of this study was to investigate the influence of unilateral bracing on the dominant ankle joint in both the braced foot and unbraced foot during running shod. The results will be compared to bilateral braced and non-braced conditions. The hypothesis of the study was that the movement of both a braced and a non-braced ankle joint would be affected by the bracing condition on the other foot.

Methods: Seven participants (height 1.81 ± 0.08 m, mass 77.3 ± 6.0 Kg Age 22.8 ± 2.9 y)who were all recreational soccer players with no history of ankle injury in the past 6 months were recruited for the study. Participants ran in a laboratory along a runway with an embedded force plate at the centre, at 4.0m/s ±5% in three different conditions; non-braced, braced dominant foot, and bilaterally braced. Running velocity was quantified using infrared timing gates Newtest 300 (Newtest, Oy Koulukatu, Finland). All kinematic data was captured by a 14 camera opto electric motion capture system (Qualisys™ Medical AB, Goteburg, Sweden). The marker configuration for this investigation used the calibrated anatomical systems technique (CAST) technique (Cappozzo et al., 1995). In order to define the segment co-ordinate system axes of the shanks and feet, retro-reflective markers were positioned on the 1st and 5th metatarsal head, and posterior calcaneus positions on the footwear, medial and lateral malleoli, medial and lateral epicondyle of the femur. Quad marker tracking clusters were securely attached to each of the shank segments. A static reference trial was obtained prior to the commencement of dynamic data collection with the participant in the anatomical position, allowing the positions of the anatomical markers to be referenced in relation to the tracking clusters, which allowed for the removal of Malleolus markers to fit the braces. Participants all wore their own shoes which they would normally wear when playing soccer. The order in which participants ran in each condition was randomized. The force plate allowed identification of foot strike and toe off and only strikes where suitable contact with the force plate were accepted for analysis (Sinclair et al., 2014).

In order to test the hypothesis of the study kinematics of the unbraced non-dominant foot with no brace on the dominant foot was compared to the unbraced non-dominant foot with a brace on the other foot. Then the kinematics of the dominant

braced foot with the other foot braced was compared to the dominant braced foot with the other foot non-braced. Paired sample t-tests were used for the specific comparisons.

Results: No significant differences ($P<0.05$) were found between the non-braced foot conditions and the braced foot conditions for peak external rotation, peak inversion and peak dorsiflexion.

Conclusion: The results suggest that the braced condition on the other foot do not influence the movement of the ankle joint in question. This research therefore suggests that ankle joints should be continued to be assessed separately when it comes to deciding whether or not to use bracing to protect the ankle from potential injury.

PO-0330

OPTIMIZATION OF DUAL COMPLEMENTARY BIOMECHANICAL VARIABLES ON STRETCH-SHORTENING CYCLE

Carlos M. B. Rodrigues [1,*]Miguel Correia [1]João Abrantes [2]Marilú Gomes [3]Marco Benedetti [4]Jurandir Nadal [5]

[1]C-BER - Centre for Biomedical Engineering Research, INESC TEC - Technology & Science Associate Laboratory, Porto, [2]MovLab – Laboratório de Tecnologias e Interfaces, Universidade Lusófona de Humanidades e Tecnologias, Lisboa, Portugal, [3]Departamento de Engenharia Biomédica, [4]Departamento de Eletrônica e Sistemas, Universidade Federal de Pernambuco, Recife, [5]PEB - Programa de Engenharia Biomédica, COPPE/UFRJ - Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Introduction and Objectives: Stretch shortening cycle (SSC) is a natural form of muscle action usually observed in gait, running and jumping as a specific and independent form of muscle action controlled by the neuromuscular system for impact anticipation, protection of structural integrity, efficiency on sub-maximal actions and potentiation on maximal actions [1]. SSC consists in a pre-stretch of activated muscle before its reversible shortening action, optimizing levels of force production and synchronizing them according to intended action.

SSC has been assessed using well-defined protocols based on maximum vertical jumps (MVJ), originally introduced by Asmussen et al. [2] and followed by numerous authors as Komi et al. [3], Bobbert et al. [4], Aragon-Vargas et al. [5] and these procedures still used today, because of its standard nature, reproducibility and simplicity. Three types of jumps are commonly analyzed, the Squat Jump (SJ), the Counter Movement Jump (CMJ) and Drop Jump (DJ) [2].

The aim of this study was to explore dual behavior of two complementary biomechanical variables, force and displacement of body center of gravity (BCG), and the resultant developed mechanical work to assess human optimization of different lower limb SSC's. In connection with this assessment, other dual biomechanical variables of BCG were analyzed for the same purpose namely force and push time for impulse analysis and force – velocity for evaluation of developed mechanical power.

Methods: Selected subjects are a small sample of n=6 healthy male students of sports and physical education degree, without any relevant sports past or previous specific training. Each subject was weighted (76.7 ± 6.7)kg, measured his height (178.9 ± 4.9)cm and performed a total of 3 trials of SJ, CMJ and DJ. During the tests, ground reaction forces were acquired with force platform AMTI BP2416-4000CE at frequency acquisition of 1000 Hz and coupled amplifier AMTI Mini Amp MAS-6.

Based on vertical ground reaction force $GRF_z(t)$ during the impulse phase it was was obtained the resulting vertical force $RF_z(t) = GRF_z(t) - Fg$ *and* vertical acceleration $a_z(t) = RF_z(t) / m$ of the BCG. From null initial velocity at inversion of vertical movement ($v_{zi} = 0$) and numerical integration of $a_z(t)$ it was obtained the vertical velocity $v_z(t)$ and numerical integration of $v_z(t)$ yielded vertical displacement $Dz(t)$ of the BCG from the initial position for each jump. By numerical temporal integration the force impulses $I[GRF_z(t)]$ and $I[RF_z(t)]$ were obtained. The propulsive mechanical power $P(t) = RF_z(t)\ v_z(t)$ and mechanical work $W(t) = RF_z(t)\ Dz(t)$ of the BCG were calculated as well as the GRF_z / Fg and RF_z / Fg.

From the above physical quantities, there were extracted a set of discrete, instantaneous and cumulative parameters with interest for this study. These were statistically analyzed with parametric and non-parametric tests, despite normality tests

due to small sample size. For this purpose IBM SPSS 9.5.0.0 was used and decisions were taken on statistical significance differences (SSD) $p<0.05$.

Results: Despite > values of *P mean up / m* at DJ than CMJ and at CMJ than SJ the values *W imp up / m* are > at CMJ than DJ and > at CMJ than SJ without SSD. This can be explained based on the fact that despite *P mean up / m* is > at DJ than CMJ and at CMJ than SJ, the time period Δt_{up} during which energy is transferred by means of mechanical power is much < at DJ than CMJ and slightly < at CMJ in relation to SJ, explaining > values of *W imp up / m* at CMJ than DJ despite > values of *P mean up / m* at DJ than CMJ and non-SSD of *W imp up / m* between CMJ and SJ despite > values of *P mean up / m* at CMJ than SJ. The same is observed with GRF_z *mean up*, Δt_{up} and $I(RF_z)$ *imp up / m* since, although GRF_z *mean up* presents > values at DJ when compared to CMJ and SJ the impulse $I(RFz)$ *imp up / m* is > at CMJ than DJ and > at SJ than at DJ in this case without SSD, which can be explained by the differences at the action time interval Δt *up* of the vertical forces at the upward phases on different MVJ.

Figure:

	SJ	CMJ	DJ
P mean up / m (W/kg)	10,59 ± 0,96	12,50 ± 1,51	24,41 ± 3,60
W imp up / m (J/kg)	3.04 ± 0.45	3.45 ± 0.29	2.75 ± 0.34
Δt_{up} (s)	0.283 ± 0.042	0.278 ± 0.039	0.113 ± 0.012
GRF_z *mean up* (N)	1421.39 ± 162,82	1474.93 ± 156.28	2357.73 ± 205.12
$I(RF_z)$ *imp up / m* (Ns/kg)	2,457 ± 0,186	2.620 ± 0,109	2,336 ± 0,139
v_z *up* (m/s)	1.365 ± 0,075	1.638 ± 0,061	1,735 ± 0,100
Δz *up* (m)	0.408 ± 0.075	0.459 ± 0.062	0.200 ± 0.027
h (flight) (m)	0.332 ± 0.045	0.364 ± 0.042	0.274 ± 0.032

Caption: Stick-figures and vertical resultant force - displacement graphs of body center of gravity for SJ (a), CMJ (b) and DJ (c)

Conclusion: By itself the higher levels of force and vertical velocity found in DJ and the larger displacements and push time found in CMJ are not sufficient to explain the differences in optimization of MVJ results expressed by h ($flight$) at each MVJ type. The current analysis shows that the process of human optimization of BCG movement at different lower limb SSC on MVJ cannot be explained based on a single discrete variable separately considered, but rather a dual optimization of complementary physical quantities such as (F_z, Δt), (F_z, Δz) or (F_z, v_z).

PO-0331

GOLF DRIVING PERFORMANCE: THE EFFECT OF DYNAMIC AND STATIC STRETCHING WARM UP ROUTINES

Graeme Sorbie [1,*] Ukadike C. Ugbolue [1] Fergal Grace [1]

[1]School of Science and Sport, University of The West of Scotland, Hamilton, United Kingdom

Introduction and Objectives: Biomechanics has been used in an attempt to find the model golf swing, with emphasis on improving performance and reducing the rate of injury [1]. Swing mechanics are described by many golf professionals as the most important factor for optimal golf driving performance [2]. Biomechanically, a high level of flexibility and ROM at specific joints and soft tissues is required to achieve the desired golf swing movement patterns [3]. Despite there being a number of different stretching techniques available to adopt as routine warm up protocols prior to competition and practice, it still remains unclear what the optimum warm up protocol should be in terms of improving the biomechanical efficiency of the golf swing. Among the various warm up protocols, dynamic and static stretches are two of the most popular stretching techniques [4]; that have been chosen to be investigated. Therefore the purpose of this study was to investigate the effect of dynamic and static stretching warm up routines using shot accuracy, distance, angle of deviation and percentage clubface contact as performance outcome measures.

Methods: A total of 12 subjects (age: 22.5 ± 3.0 years; mass: 80.3 ± 6.4 kg; height: 1.84 ± 0.1 m), volunteered to take part in the study. All subjects held a Council of National Golf Unions (CONGU) handicap of 5 or less (1.4 ± 1.9). Prior to commencing testing, approval for the study was obtained from the School of Science & Sport, University of the West of Scotland, UK, Ethics Committee. Each subject was required to attend 2 separate sessions on non-consecutive days. The testing lasted an average of 2 hours over a 3 / 5 day period. The three different components tested were carry distance, accuracy and ball contact using a driver. Each subject was randomized to either a dynamic stretching or static stretching routine on their first day of testing. The opposite routine was then performed on the final testing session. Each testing session began with a 5 minute run at 40% of their perceived maximum running speed around the practise area. This was based on a study by Yamaguchi et al. [5]. The stretching protocols consisted of 9 stretches targeted at the upper and lower body. The markings on the fairway ranged from 150-300 yards. Accuracy was measured by the absolute distance each shot deviated, left or right, from the predetermined target line. Measurement recordings were taken from the teeing area to the final resting position of the ball. Club contact with ball data was based on how well the ball was hit. Participants responded either with “yes” for good contact or “no” for poor contact. Descriptive statistics and paired t-tests were performed ($P = 0.05$) between the dynamic and static stretching protocols.

Results: Within participants there was a significant difference between driving distance after performing the dynamic stretch and static stretch ($P = 0.012$). Driving accuracy produced a significant difference between participants after the dynamic and static warm up ($P = 0.049$). Within participants the driving distance coefficient of variation after the dynamic and static stretch protocols were- range: 2.55% - 7.09% and range: 1.88% - 7.37% respectively. Also within participant there was a greater variability in the shot accuracy after the dynamic stretch protocol (Mean (SD): 55.77 (9.29) %) compared with the static stretch protocol (Mean (SD): 49.83 (12.18) %). The results also showed no significant differences between the angle of deviation outcome measure.

Caption: Summary of Driving Performance Results

Conclusion: The current study is the first to report that with a driver a dynamic general warm up will enhance driving performance over a static general warm up routine. It is worth noting, that Moran et al. studied dynamic stretching versus static stretching and no stretching prior to testing similar variables with a 5 iron. Their protocol was different and outcome measures were club head speed and ball speed [4]. A more scientific approach was adopted where the distance of each shot, clubface angle and swing path were calculated to measure accuracy. The results demonstrate that dynamic stretch could significantly increase driving distance and accuracy in comparison to static stretch. However, no significant difference was displayed in club contact with the ball between the dynamic and static stretching protocols. Although the sample size was small and no control group was used, we anticipate that the outcome of this research study provides useful data to amateur and professional golfers who engage in stretching techniques during training.

EQUINE SURFACE ROTATIONAL RESISTANCE MEASUREMENT

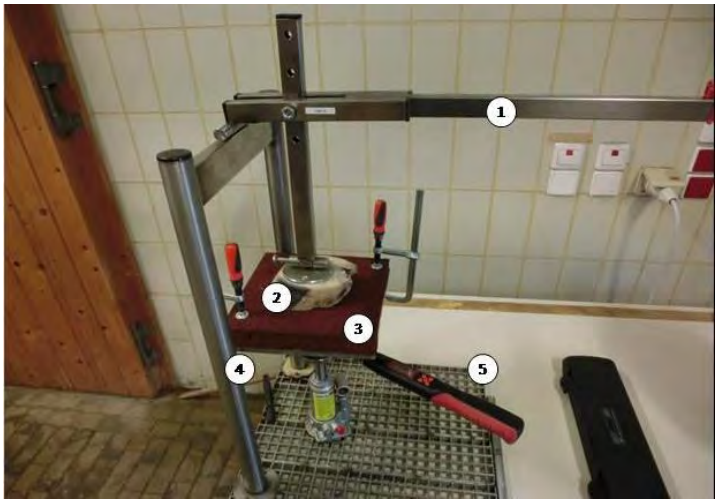
Johannes P. Schramel [1,*]Christian Peham [1]

[1]Equine clinic, Movement Science Group, Vienna, Austria

Introduction and Objectives: In recent years, manufacturers and embodiments of equine arena surfaces and floorings for horse caring have increased significantly. Surface functional properties and methods for their assessment are still under discussion and subjective opinions of riders and experts replace missing guidelines. It is commonly accepted that some surface characteristics assist in achieving optimal performance but may also reduce or enhance the risk of injuries.
The interaction between hoof and ground is complex and varies depending on gait and riding discipline. In particular, horse races and show jumping exerts high loads to the horse´s legs that may be strongly influenced by surface attributes. Many studies investigate shock absorption and energy restitution with equipment that mimics the footing of a horse. Some apply vertical forces in combination with tangential (shear) forces to simulate slipping after impact. However, also the rotational resistance (RR) between the surface and the hoof is an important functional property. It mimics loads occurring in show jumping where heavy landings together with sharp turns happen frequently. The latter is considered a major stress for joints, tendons and ligaments and may result in even fatal injuries. On the other hand a too small RR can cause unsafe movements and ligamental strain. Moving repeatedly on a circle in horsewalkerswith a high RR rubber floor may compromise soundness in the long term. The same holds for performing canter pirouettes on high friction grounds where excess loading may occur from a rotating limb and fixed foot. Aim of the study is the development of a RR test equipment that enables assessment of the maximum torque between a surface and a loaded hoof.
Methods: Rotational resistance was measured with a custom-made device (Fig. 1). A weight- loaded lever (1) applies a constant force of 1000N vertically to a natural horn capsule (2) of representative size and shape (15cm x 12cm). The latter was pivoted in the midline to achieve flat contact with the surface. The probe to be tested (3) was located on a turntable (4) that can be adjusted in height to set the lever (1) to a horizontal position. Granular material like sand was filled into a bucket up to about 15-20 cm height and then put on the turntable. A digital torque wrench (5) with max-hold function (DTW-100f CHECKLINE Europe) was attached to the turntable to measure the maximum torque (Nm) at the transition from static to kinetic friction between surface and hoof. Each sample was measured six times (turf 11 times) to derive mean value and standard deviation with Microsoft Excel. The value of the first rotation was discarded. Moisture content of granular material was measured with a TRIME PICO 64 HD2 (IMKO Germany) sensor. Compliant surfaces were levelled before every measurement and the hoof was reset to plane position. The angle of rotation was between 15 ° and 45 ° until a stable reading of the torque meter was achieved.
Descriptive statistics was applied and results were compared with turf by ANOVA. Level of significance was set to $p<0.05$.
Results: Nineteen surfaces for riding areas and for horse caring have been measured. The results of the RR in comparison to turf are depicted in table 1. Moisture content was between 8% and 15%. Turf had a higher RR than some surfaces designed for equitation. High RR was also recorded for dry wooden shavings used for horse bedding.

Sands without supplements showed smaller RR. Rubber based surfaces revealed greater or equivalent RR than turf. In contrast, a piece of oak wood and plastic grid not filled with grit showed low RR revealing a slippery surface.

Figure:



Caption: Test equipment for rotational resistance of surfaces

Conclusion: The proposed method to determine RR of equestrian surfaces seem to be suitable to compare sand and rubber - based materials with turf and may assist the design of suitable riding surfaces by combining versatile materials and supplements. The equipment may also be used to test horse shoeing concepts on multiple grounds.

Table:

Surface	Mean	SD	Significance
Turf	370.1	50.2	Reference

KINEMATIC CHANGES DURING A 30-REPETITION BOUT OF THE BARBELL POWER CLEAN

Paul Swinton [1,*] Katherine Burgess [1] Eimear Dolan [1] Rodrigo Aspe [2]

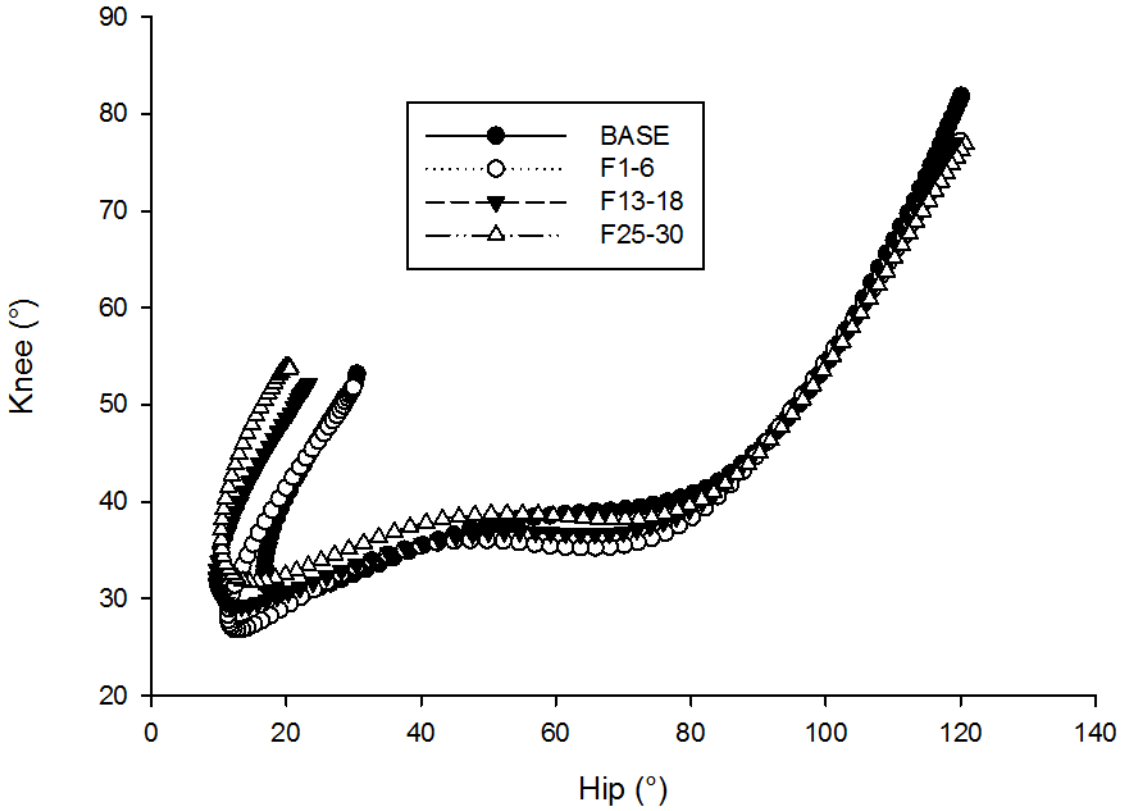
[1]School of Health Sciences, Robert Gordon University, Aberdeen, [2]School of Sport and Exercise, University of Gloucestershire , Gloucestershire , United Kingdom

Introduction and Objectives: Recently, there has been increased popularity of high intensity training programs performed with technically demanding resistance exercises. Despite improvements in fitness and body composition that can be obtained over short time periods with such training practices, many exercise professionals and researchers have raised concerns regarding the safety of performing complex resistance exercises during states of extreme fatigue. The purpose of this study was to quantify and compare the kinematics of the lower extremity when well-trained athletes perform a fatiguing and non-fatiguing protocol with a technically demanding resistance exercise to provide mechanical insights into the associated injury potential.

Methods: Sixteen male and four female resistance trained participants performed 30 repetitions of the power clean using a gender specific absolute load (males: 62 kg, females: 41 kg) in as short a duration as possible. To provide a baseline assessment of kinematics, a non-fatiguing protocol comprising 6 repetitions (with inter-repetition rest periods of 10 seconds) was performed with the same absolute load. Kinematics were quantified using 2-dimensional video analysis of the hip, knee and ankle in the sagittal plane. Discrete kinematic variables comprised joint angles measured at the beginning (start of the first pull) and end of each repetition (the point where the barbell touched the shoulder during the catch phase). In addition, the coordinated action of the hip and knee were quantified using angle-angle plots and a vector coding method that produced a coupling angle describing the relative movement as: 1) Hip dominant; 2) In-phase; 3) Knee dominant; or 4) Anti-phase. To assess the effects of fatigue on kinematics, the variables measured were averaged across blocks of six repetitions. The first block comprised the baseline assessment (BASE), the second block comprised the first six repetitions of the fatiguing protocol (F1-6), the third block comprised the thirteenth to eighteenth repetitions of the fatiguing protocol (F13-18), and the fourth block comprised the final six repetitions of the fatiguing protocol (F25-30). Potential differences between the blocks of repetitions were analysed using a one-way repeated measures ANOVA. Effect sizes were calculated using the eta squared statistic (n^2), with values of 0.02, 0.13 and 0.26 used to indicate a small, medium and large effect, respectively.

Results: Analysis of the discrete kinematic data identified significant differences in joint angles adopted at the start and end of the power clean (Table 1). The results demonstrated that as fatigue accumulated participants reduced the amount of knee flexion ($p<.001$, $n^2=.045$) at the beginning of the movement and reduced the amount of hip flexion ($p<.001$, $n^2=.040$) and ankle dorsiflexion ($p=.036$, $n^2=.044$) at the end point of the movement. Analysis of coupling angles demonstrated no significant differences in the distribution of the coordination phases across the repetition blocks ($p=0.199$ to $p=0.069$; $n^2=.040$ to $n^2=.097$, Table 1).

Figure:



Caption: Figure 1. Angle-angle diagram displaying the relative hip and knee motion averaged across subjects.

Conclusion: The results of the present study demonstrate that a fatiguing protocol representative of that used in popular high intensity resistance training programs has the potential to cause statistically significant changes in the kinematics associated with a complex exercise. It appears that the kinematic changes observed occur as a result of the fatigue developed and potentially the task constraint of attempting to complete the prescribed number of repetitions in as short a duration as possible. However, it is important to note that the change in kinematics observed were relatively small in magnitude compared with the variation across individuals performing the same movement. That is, effect sizes calculated for all kinematic variables demonstrating statistically significant differences were classified between small and moderate. Interestingly, the majority of participants demonstrated the ability to maintain the salient feature of coordinating the action of the hip and knee despite the fatigue elicited. Collectively, the results suggest that well trained athletes can perform complex resistance exercises in states of extreme fatigue and still maintain appropriate kinematics to reduce the likelihood of incurring injury.

Table:

	BASE	F1-6	F13-18	F25-30	*p*	n^2
Initial hip (°)	121±8	120±9	119±8	120±8	.58	.004

PEDALING SYMMETRY DURING TWO TYPES OF INCREMENTAL MAXIMAL CYCLING PROTOCOLS

Rodolfo A. Dellagrana [1,*]Luis Antonio Pereira de Lima [1]Felipe P Carpes [2]Fernando Diefenthaeler [1]

[1]Biodynamic Research Group, Federal University of Santa Catarina, Florianópolis, [2]Applied Neuromechanics Research Group, Federal University of Pampa, Uruguaiana, Brazil

Introduction and Objectives: Pedaling asymmetry was observed among mountain bike (MTB) cyclists performing protocols of simulated cycling [1,2]. For both prolonged [1] or incremental workload [2] MTB cyclists presented pedaling asymmetries related to exercise intensity, in which higher intensities elicited smaller asymmetry indexes. It is know that MTB and road cycling are very different cycling disciplines and although they share some characteristics, there are some important biomechanical differences between them [3]. It is not clear if pedaling asymmetries that may exist among road cyclists could be related to exercise intensity as observed in MTB. In this study, we investigated if pedaling asymmetry in peak torque is observed among road cyclists and analyzed whether asymmetry can be related to exercise intensity.
Methods: Eighteen road cyclists with more than two years of training experience volunteered for this study (age: 25 ± 8 years; body mass: 70.6 ± 7.7 kg; height: 177 ± 4 cm; body fat: 9.3 ± 4.7 %). Cyclists performed two incremental cycling trials (step and ramp) to exhaustion in two separate days within 48h. Protocols were randomized and both trials were performed on an electromagnetically braked cycle ergometer. Both tests started at initial workload of 100 W. In the step type test, workload was increased 30 W every 3 minutes, whereas in the ramp type workload continuously increased resulting in 30 W every minute. Pedaling cadence was their preferred. Leg preference was determined by using the Waterloo inventory. The maximum crank torque average (MT) of 11 subsequent pedaling cycles were bilaterally determined using a pair of instrumented cranks for every workload stage. Asymmetry index (AI) was calculated using equation by Chavet [4]. Data normality was verified by Shapiro-Wilk test. Descriptive statistics (mean and standard deviation), and both independent t-test and Mann-Whitney test were utilized to compare preferred and non-preferred limbs. Significance level was set at 5%.
Results: In general, road cyclists were symmetric for MT regardless of the testing protocol. A single pedaling asymmetry was observed during the ramp protocol at stage of 250 W (Figure 1). Additionally, average AI in each stage presented ranged from 3.35 to 4.85 % in the step test, and 3.90 to 6.70 % in the ramp test. Different results were found to MTB cyclists, in which pedaling asymmetry was intensity dependent [2]. This difference may be explained by the competition and training configuration. For example, MTB presented different pattern of sagittal plane kinematics at the ankle when compared to road [5], which may have implication for maximal as measure here.

Figure:

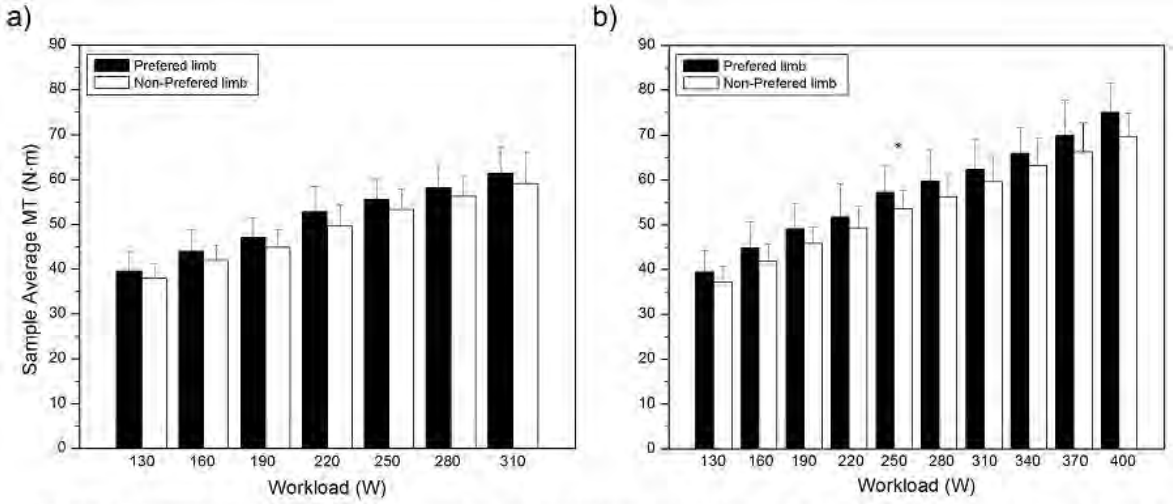

Figure 1. Maximum crank torque average (MT) for preferred and non-preferred leg during the step (a) and ramp (b) trials. * significant difference in MT between preferred and non-preferred leg.

Conclusion: Road cyclists submitted to incremental cycling testing with different condition of load delivery were symmetric concerning MT. A single asymmetry was observed at stage of 250 W for one of the test and its meaning needs further investigation. Moreover, AI was less than 10% in all stages to both incremental tests.

FOUR WEEKS OF HIGH-INTENSITY INTERVAL TRAINING USING CONTINUOUS VERTICAL JUMPS INCREASES THE POWER OUTPUT AND JUMP HEIGHT

Jonathan Ache Dias [1,*] Rodolfo André Dellagrana [1] Anderson Santiago Teixeira [2] Antônio Renato Pereira Moro [1]

[1]Biomechanics Laboratory, [2]Physical Effort Laboratory , Federal University of Santa Catarina, Florianópolis, Brazil

Introduction and Objectives: Several types of jumps has been routinely used in athletic evaluation and training. In general, have been suggested that vertical jump training increases the jump height [1]. The continuous vertical jumps test was proposal initially to measure mechanical power output [2] and recently to evaluate the anaerobic fitness [3]. However, in our knowledge, no studies have evaluated the use of continuous vertical jump as a mode of high-intensity interval training, like used in other exercise modes such as cycling [4]. The objective of this study was to verify the effect of continuous jump interval training on kinetic and kinematic variables of continuous jump test.

Methods: Eighteen recreational runners (age = 27.8 ± 4.4 years), ten women and eight men, participated of this study. They were divided randomly in two groups according to peak velocity, determined in a maximal incremental test performed in treadmill. Groups: Control (body mass = 66.3 ± 13.9 kg) and Experimental (body mass = 63.1 ± 10.1 kg). The training program was conducted in four weeks. During this time all participants performed, three times for week, a basic training consisted of 40 minutes of treadmill running at 70% of peak velocity. In separate days, the experimental group underwent to a complementary training that was consisted of eight sessions, distributed in the four weeks, of four to six repeats of 30 s of continuous vertical jumps. The repeats was performed with maximal effort (all-out) and five minutes of recovery between repeats (active = 2:30 of treadmill walking at 4 km/h and 2:30 of passive recovery) was adopted. Two days before and after the training program one repeat of 30 s of maximal continuous vertical jumps was performed as evaluation using a force platform (Quattro Jump 9290BD, Kistler, 500 Hz) and a video camera (Canon SX510B, 120 Hz). From vertical ground reaction force of each jump was measured the peak force (PF) and peak power output (PP). From kinematic analysis was analyzed the jump height (JH) and the lowest point of maximal vertical displacement of center of mass (hc). The vertical stiffness was calculated as follow: Kvert = PF/hc. All variables were analyzed from the mean of all jumps performed in 30 s. A mixed model ANOVA (Split-plot) with a between participants (groups: experimental and control) and within participants (time: before and after training) variables was used with a level of significance of 5%. The simple effects was analyzed by independent and paraded t-test with a level of significance of 1% (Bonferroni correction).

Results: The participants performed approximately 25 jumps during each repeat of 30 s of continuous jumps in both training and evaluations. Table 1 shows the descriptive statistics of the continuous jumps test and indicate the significant paired comparisons. The analysis of variance revealed main effect of time ($\mu_{JH} = 0.28$; $F_{JH} = 6.48$; $p_{JH} = 0.02$; $\mu_{PP} = 0.38$; $F_{PP} = 9.83$; $p_{PP} = 0.06$) and interaction groups *vs* time ($\mu_{JH} = 0.4$; $F_{JH} = 10.9$; $p_{JH} = 0.004$; $\mu_{PP} = 0.36$; $F_{PP} = 9.28$;$p_{PP} = 0.08$) for JH and PP. These results suggest that four weeks of the jump training increases the JH (10.1%) and PP (9.6%). PF and Kvert do not presented any effect of group ($F_{PF} = 0.77$; $p_{PF} = 0.39$; $F_K = 2.13$; $p_K = 0.16$), time ($F_{PF} = 0.5$; $p_{PF} = 0.48$; $F_K = 0.86$; $p_K = 0.36$) or interaction ($F_{PF} = 2.1$; $p_{PF} = 0.16$; $F_K = 0.33$; $p_K = 0.56$).

Conclusion: The continuous jump interval training is able to increase the jump height and power output without alterations in peak force and stiffness. This training mode may be an alternative to improve the power output of athletes from different sports.

Table:

	JH (cm)	PP (w)	PF (N)	Kvert (kNm)
Control BT	32.92 ± 5.68	2586.00 ± 893.50	1354.55 ± 465.41	5.29 ± 2.21
Experimental BT	30.15 ± 5.69*	2191.05 ± 679.43*	1142.38 ± 367.19	4.28 ± 1.37
Control AT	32.52 ± 5.22	2589.01 ± 868.60	1358.93 ± 324.92	5.23 ± 1.51

RELATIONSHIP BETWEEN SWIMMING MEAN VELOCITY ANT TWO DYNAMOMETRY TESTS: THE TETHERED SWIM TEST AND THE PARTIALLY SWIMMING TEST.

Bruno Mezêncio [1,*]Rafael Soncin [1]Joao Claudino [1]Joao Pedro Pinho [1]Juliana Pennone [1]Ana Paula Azevedo [1]Alberto Carlos Amadio [1]Julio Serrão [1]

[1]Laboratory of Biomechanics, USP, São Paulo, Brazil

Introduction and Objectives: The propulsive force as well as the swimming technique, are determinants factors on swimmer performance [1]. Among the methods used to evaluate this force during the swimming, the tethered swimming test can be highlighted like a valid and specific test [2,3]. Nevertheless, in this test swimmers are not affected by the drag force. Another way to test swimming force, which incorporates the effect of a drag force, is by the partially tethered swimming. However there is a disagreement in the scientific literature about the relationship between the partially tethered swimming and swimming performance [4,5]. Thus the aim of the study was compare the relationship between these tests (tethered and partially tethered swimming) and the swimming performance.

Methods: Twelve male swimmers with experience higher than five years on swim (22.6 ± 3.8 years, 1.75 ± 0.06 m, 74.3 ± 4.9 kg e 26.1 ± 1.3 s as best time on 50m free style) performed five repetitions of free swim tests, tethered swim test and partially tethered on random order with 5' of rest interval between the tests.

On free swim test a maximal 25 m crawl sprint without breathing was performed starting from inside the pool, and was recorded by a camcorder (A602fc-100fps, *Basler*, Germany). On tethered swim test, each swimmer used a waist belt connected to a steel cable fixed on a load cell with sampling frequency of 1000 Hz (Interface, Noraxon, USA). In the partially tethered swimming test the system used in the tethered swimming test, composed by the steel cable and load cell, was attached to another steel cable passing through a pulley fixed at a starting block, which worked by a geared motor (RX-400, Ringcone, Brazil). This configuration allowed the test velocity to be controlled in 0.6 m/s. In both dynamometry tests the swimmer should perform the higher possible effort without breathing for 10 stroke cycles. The force data was registered during all tests, however it was analyzed the fourth to the eighth stroke cycle.

The video data was analyzed on software SIMI *motion* 7.0 (SIMI Reality Motion Systems, Germany). The force data was treated on software Matlab 2009b (Math Works, EUA) where was filtered with low pass filter type Butterworth 6ª order with cut-off frequency of 16Hz. There was calculated the mean propulsive force of the stroke cycles for both dynamometry test and the mean velocity for free swim test. In order to relate the force data with the swimming mean velocity a linear regression was performed for each dynamometry test. The correlation coefficient (r) and the determination coefficient (r^2) were calculated for each equation. The significance level adopted was $\rho<0.05$.

Results: The mean velocity on free swim test was 1.83 ± 0.16 m/s, the mean force during the tethered swim was 111.91 ± 17.12 N and during the partially tethered swim was 97.43 ± 16.11 N. The regression analysis results are presented in Table 1.

Conclusion: The force evaluated by both tests presented significant correlation with the mean swimming velocity, however the intercept coefficient of both tests are high. This indicates that both tests are very influenced by unknown factors. The detection of these factors can improve the effectiveness of the tests to evaluate the swimming performance.

Table: Table 1 – Intercept, Slope, correlation coefficient (r), coefficient of determination (r^2) and confidence interval (CI 95%) for the regression equation

Models	Intercept (CI 95%)	Slope (CI 95%)	r - (r^2)
Tethered Swim	0.774 (0.328 - 1.231)	0.010 (0.006– 0.014)	0.847* - (0.717)
Partially Tethered Swim	1.011 (0.542 - 1.431)	0.082 (0.031 – 0.126)	0.791* - (0.625)

COMPARISON OF CENTER OF PRESSURE TRAJECTORY CHARACTERISTICS IN TABLE TENNIS DURING TOPSPIN FOREHAND LOOP BETWEEN SUPERIOR AND INTERMEDIATE PLAYERS

Y Zhang [1,*] Y Gu [1] J S Li [1] J Baker [2]

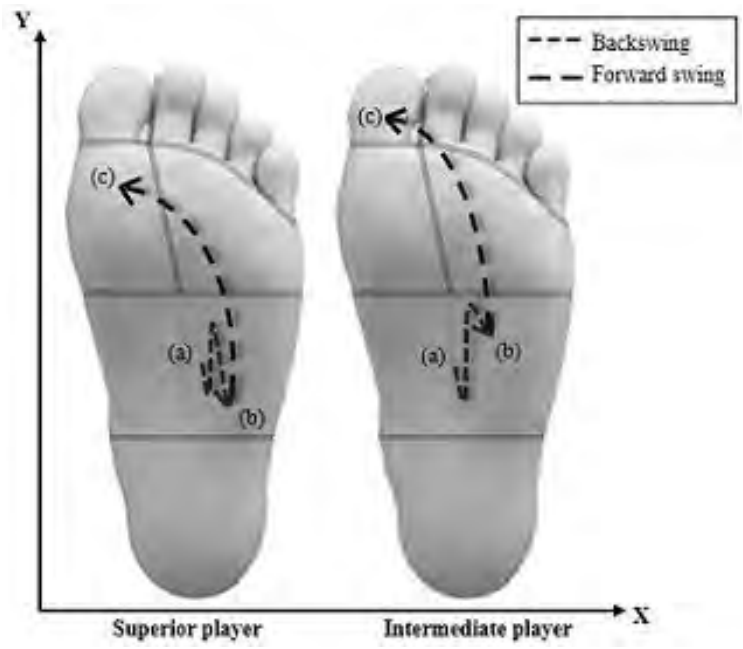
[1]Faculty of Sports Science, Ningbo University, Ningbo, China, [2]Faculty of Science and Technology, University of the West of Scotland, Glasgow, United Kingdom

Introduction and Objectives: Several previous studies have reported that momentum generation depends on foot drive largely in striking motions. Based on this case, the purpose of this study was to investigate the differences in the center of pressure (COP) trajectory under the dominant foot during forehand loop between superior and intermediate players. The whole motion was divided into two key events: backswing and forward swing corresponding to the stage from preparation to backward-end and the stage from backward-end to forward-end, respectively. Variables as COP anterior-posterior displacement (D_x), medial-lateral displacement (D_y), and velocity ratio between forward swing and backswing ($R_{f/b}$) were included.

Methods: Thirteen superior (national Division I) and thirteen intermediate (national Division II) male table tennis players volunteered to participate in this study. Novel Pedar insole plantar pressure measurement system (Novel GmbH, Munich, Germany) was used to record COP trajectory. A ball machine projected topspin balls directly to the foreside of the subject's court. All subjects were required to perform single crosscourt forehand loop with maximal power wearing unified training footwear. At least five successful trials were performed for one subject. Independent samples t-test were taken for each dependent variable. The level of significance was set at $p < 0.05$.

Results: Dx of superior players at backward-end located more laterally compared with that of intermediate players. No significant difference was found in Dx at forward-end between two skilled levels. Dy of superior players was obviously smaller at backward-end and forward-end. The data of Rf/b for superior group was significantly higher than the intermediate group. At backward-end, superior players transferred body weight more sufficiently to the racket-side resulting in larger Dx, which may facilitate momentum generation and distal velocity. Dy for the intermediate group located closer to the forefoot region, suggesting that the heel was off the ground, and this may decrease stability of players during this stage. At forward-end, D_x would not be influenced by skilled level. The smaller D_y of superior players contributes to resume to preparation for the next stroke. In addition, for superior players, the slower COP shift velocity during backswing provided a more stable basis for the following stage. While the faster velocity during forward swing related to a forceful lower limb drive which was considered as the "starting point" of kinetic chain.

Figure:



Conclusion: Significant differences between two skilled levels were found in D_x during backswing, D_y during both backward and forward swing and $R_{f/b}$. The key results indicated that superior players possessed better ability of motion control and technique manipulation. Table tennis coaches and players should pay more attention to stability training and enhancing push-off effect.

PO-0339

HOW CAN WE MONITOR PASSIVE DRAG IN COMPETITION SETTINGS?

Tiago M Barbosa [1,*]Jorge E Morias [2]Henrique Neiva [3]Pedro Forte [3]Nuno D Garrido [4]Daniel A Marinho [3]

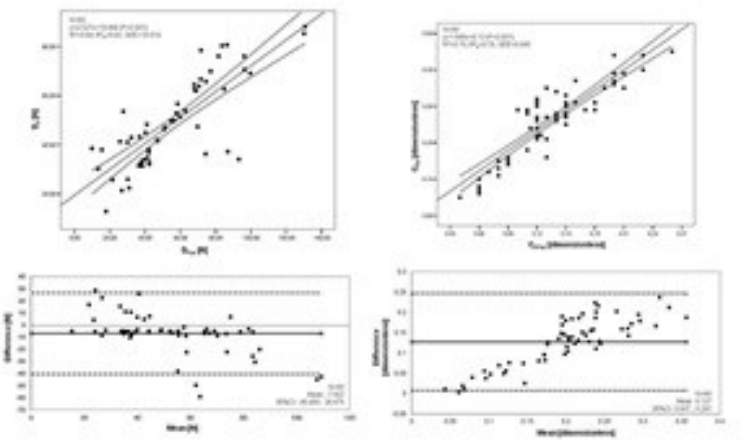
[1]Nanyang Technological University, CIDESD, Singapore, Singapore, [2]Polytechnic Institute of Braganca, CIDESD, Braganca, [3]University of Beira Interior, CIDESD, Covilha, [4]University of Tras-os-Montes and Alto Douro, CIDESD, Vila Real, Portugal

Introduction and Objectives: Swimming rules do not allow instrumenting the swimmer during an official event. Therefore there is the need of a valid, straightforward, quick and affordable way to monitor the passive drag in competition settings. The aim was to compare the passive drag assessed with experimental and analytical procedures

Methods: Sixty young swimmers (30 boys and 30 girls with approximately 12-13-y) part of a national talent ID scheme were assessed. The passive drag was assessed experimentally with inverse dynamics of the gliding decay speed [1]. Swimmers were invited to perform a maximal push-off on the wall fully immersed and glide in the streamlined position. A speedo-meter cable (Swim speedo-meter, Swimsportec, Hildesheim, Germany) was attached to the swimmer's hip and the gliding velocity decay was acquired (f=50Hz). After numerical differentiation of the filtered speed-time curve, with the anthropometrical and inertial parameters collected beforehand (height, body weight, surface areas), the passive drag (Dp) and passive drag coefficient (CDp) were computed. The theoretical modeling included a set of analytical procedures based on naval architecture [3]. The Dp is the sum of friction drag and pressure drag. The friction drag was estimated based on its coefficient determined from the ITTC-57 correlation line for turbulent flow and the wetted surface. Pressure drag was assumed to be due to bluff body separation, with viscous pressure resistance due to boundary layer growth negligible. Pressure drag was calculated based on the frontal surface area measured with a photogrammetric technique and retrieving the pressure drag coefficient from numerical simulation studies [2]. Simple linear regression models and Bland-Altman analysis were computed between experimental and analytical procedure.

Results: Linear regression models showed a high adjustment for both Dp (R^2=0.64; R^2_a=0.63; SEE=16.436; $P<0.001$) and CDp (R^2=0.79; R^2_a=0.78; SEE=0.021; $P<0.001$). On average the bias between procedures was -7.002N (95%CI: -40.480; 26.475) for the Dp and an overestimation of 0.127 (95%CI: 0.007; 0.247) for the CDp. Figure 1. Comparison between experimental and analytical procedures to assess the passive drag (Dp and Df+pr, respectively) and the passive drag coefficient (CDp and CDf+pr, respectively).

Figure:



Conclusion: As a conclusion, there is a strong relationship in the Dp and CDp between experimental and analytical procedures. Analytical procedures are a novel, feasible and valid way to gather insight about one's passive drag during competition settings.

PO-0340

COMPARISON OF CLASSICAL KINEMATICS, VARIABILITY AND NONLINEAR PARAMETERS FOR THE FOUR COMPETITIVE SWIMMING STROKES

Tiago M Barbosa [1,*] Mario J Costa [2] Jorge E Morais [3] David Prendergast [4]

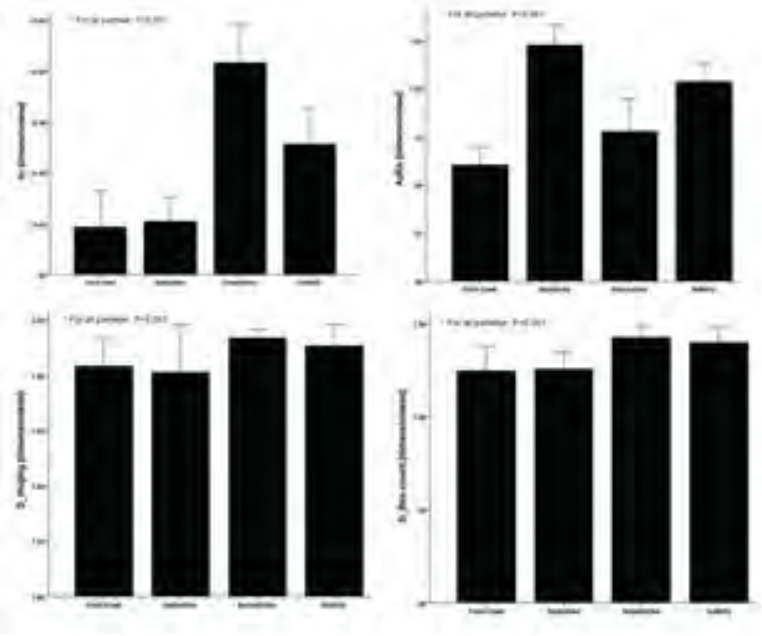
[1]Nanyang Technological University, CIDESD, Singapore, Singapore, [2]Polytechnic Instiute of Guarda, CIDESD, Guarda, [3]Polytechnic Instiute of Braganca, CIDESD, Braganca, Portugal, [4]University of Buffalo, Buffalo, United States

Introduction and Objectives: The aim of this research was to compare classical kinematic and nonlinear parameters in the four competitive swimming strokes.

Methods: Twenty-one national level swimmers (11 boys and 10 girls; 13.61±1.3-y) performed a set of 4×25 m swims from a push-off start with the front-crawl, backstroke, breaststroke and butterfly stroke in random order. A speedo-meter (Swimsportec, Hildesheim, Germany) was attached to the subjects' hip (f=50Hz) to determine instantaneous velocity. Data were exported to a signal processing software (AcqKnowledge, Santa Barbara, USA). Velocity fluctuation (dv) was selected as a classical kinematic parameter and based on previous studies, is also considered an energy cost estimator [1]. For the non-linear analysis, ApEn was calculated for at least 700 pairs of speed-time, an embedding dimension of m=2 and the maximum tolerance value of r=0.1 [2]. The D was calculated by the Higuchi's method (D_ Huijing) from the speed-time pairs and complemented with the Box-count method (D_Box-count) [3]. Repeated measures (within-subjects ANOVA) analysis was performed (P≤0.05).

Results: Fractal properties were 1.80±0.86 - 1.93±0.02 for D_ Huijing and 1.24±0.07 - 1.42±0.03 for D_Box-count (Fig 1). There were significant variations among the four swimming strokes for dv [$F(1,21)=620.99$; $P<0.001$], ApEn [$F(1,21)=296.50$; $P<0.001$], D_Huijing [$F(1,21)=87.86$; $P<0.001$] and D_Box-count [$F(1,21)=207.81$; $P<0.001$]. Post-hoc testing showed that all possible pairwise combinations were significantly different ($P<0.001$). Overall, the lowest values were observed for front-crawl; followed by the backstroke, butterfly stroke and breaststroke (Fig 1). Conversely, within-subject testing controlling the effect of velocity (ANCOVA) did not demonstrated significant interactions for the dv [$F(1,20)=0.12$; $P=0.91$], D_Huijing [$F(1,20)=0.001$; $P=0.97$] and D_Box-count [$F(1,20)=0.05$; $P=0.83$] but did for the ApEn [$F(1,20)=4.96$; $P=0.04$].

Figure:



Conclusion: Human swimming with all four competitive strokes showed fractal properties (1≤D≤2). More predictable swimming patterns (i.e. ApEn) have a lower level of complexity (D) and this might have an effect on the energy cost of swimming based on the observed dv. Figure 1: Comparison of the classical and nonlinear parameters between the swim strokes (mean±2SD).

THE RERATIONSHIP BETWEEN THE GLIDE DISTANCE AND SWIMMING SPEED IN THE COMPETITIVE SWIMMERS

Tadashi Wada [1,*] Yuya Horihata [2] Noriyuki Yamamoto [3] Yukinori Shintaku [4] Yu Kashiwagi [2] Kazuo Funato [2]

[1]Kokushikan University, [2]Nippon Sport Science University, Tokyo, [3]Japanese Red Cross Hokkaido College of Nursing, Hokkaido, [4]Biwako Seikei Sport College, Ohtsu, Japan

Introduction and Objectives: Improvement in swimming performance is not only associated with stroke technique but also with the gliding movement during the start and turn phases. Furthermore, it is important that the momentum created by a swimmer in swimming direction is larger than against swimming direction. Passive drag is produced by measuring the force necessary to tow a swimmer through the water at a constant speed with his body in a prone position [1]. The underwater gliding and dolphin kick movement during the start and turn phases are important for the total race time in modern swimming [2, 3]. The study was designed to analyze the findings of underwater electromyography of lower limb muscles during the underwater dolphin kick movement in competitive collegiate swimmers.

Methods: Seven healthy male competitive swimmers volunteered to participate in this study (age: 22.0±3.8yrs, height: 173.4±6.9cm, body weight: 71.3±7.9kg, athletic career: 13.7±3.9yrs). The subjects performed underwater gliding movement at maximum speed after pushing off from the start wall. In addition, three types of underwater gliding movement [Prefer distance, Short distance and Long distance] were performed with maximum effort. The subjects were monitored through an underwater video camera with a sampling frequency of 60 Hz in the sagittal plane to measure the angular displacement of their different joints. A wireless electromyography system (Biolog DL-5000, S&ME, Japan) was used to collect the muscle activities from the vastus lateralis, hamstrings, tibialis anterior, and gastrocnemius. Speed Meter (Vine Co., Japan) was used to measure swimming speed, and a motion analysis system (Frame-DIAS4; DKH, Japan) was used to digitize body landmarks.

Results: Among the underwater gliding movement distance types, the swimming speed of the prefer distance was the fastest (prefer distance: 2.22 m/sec; long distance: 2.10 m/sec; and short distance: 2.19 m/sec, $P < 0.05$). The rectified EMG findings showed that gastrocnemius and hamstrings muscle activities of elite swimmers were higher than non-elite swimmers during these movements. However, elite swimmers had no muscle activity in the tibialis anterior.

Conclusion: The main finding of this study is that the gliding movement of long distance was significantly slower in the swimming speed than short and prefered distance. In addition, prefered glide distance was the fastest swimming speed. The present study results suggested that there was the most prefered glide distance to get the maximum swimming speed after a start and a turn.

PO-0342

PREDICTION OF INJURY RATES USING TURNOUT VARIABLES IN CONTEMPORARY DANCERS

Joanna Jenkins [1,*] Matthew Wyon [2] Alan Nevill [2]

[1]London Metropolitan University, London, [2]Wolverhampton University, Wolverhampton, United Kingdom

Introduction and Objectives: Turnout has both an aesthetic appeal and functional implications and over the past two decades has been the subject of some debate as to the requirements and implications of “appropriate” turnout. To achieve the 180° of turnout, which dancers strive for, other structures of the lower limb, in addition to the hip, contribute. Research has suggested that dancers may be more at risk of injury when they excessively utilise non-hip components of turnout to compensate for deficits in hip external rotation when trying to achieve maximal total turnout. However, numerous different measures of turnout have been cited in the literature as well as suggestions for derived variables to account for shortfalls in particular components of turnout. The objective of this study was to assess whether measurements of turnout can predict the number of injuries ([0 or 1 injury] or [2+ injuries]) incurred over a 10 month period.

Methods: At the beginning of the academic year 47 female, full-time contemporary dance students (age 19.9 ± 2.51 years; height 1.65 ± 0.05 cm; weight 56.23 ± 6.51 kg) were screened as part of a bi-annual screening process. Measurements, summed of both legs, were obtained for passive hip external rotation (pER), total passive turnout (TPT) and total active turnout (TAT). From these, three further variables were derived; compensated turnout, muscular turnout and active ER lag. At the end of a 10 month period the number of injuries reported by the dancers to a physiotherapist were obtained for the previous 10 months.

Results: Binary regression carried out on all six turnout variables identified a significant positive effect of both compensated and muscular values, on the probability/odds of being in the 2+ injury group. For every 1% increase in compensated and muscular values, there was a corresponding 9% and 8.4% increase, respectively, in the odds that the dancer would sustain 2 or more injuries compared to 0 or 1 injury.

Conclusion: The findings of this study support previous findings that dancers with a greater difference between passive hip ER and total lower limb turnout are more at risk of injury. However, the present study quantifies this risk. It also emphasises the need to assess not only the hip pER but ensure comparisons are made with TPT and TAT. Screening compensated and muscular values may be useful to address shortfalls to prevent injuries in the future.

PO-0343

A BIOMECHANICAL INVESTIGATION OF THE USE OF HEEL WEDGES DURING SQUATS PERFORMED BY RECREATIONALLY TRAINED MALES WITH OR WITHOUT LIMITED DORSIFLEXION

Paul Swinton [1,*]Swatik Mahendra [1]

[1]School of Health Sciences, Robert Gordon University, Aberdeen, United Kingdom

Introduction and Objectives: The squat is one of the most frequently used forms of lower body resistance exercise in both athletic and rehabilitation settings. The widespread use of the movement is primarily based on its similarity to activities performed in daily living and in various sports. A large number of research studies have previously investigated kinematics and kinetics of the squat from both a performance enhancement and injury risk perspective. To perform the squat appropriately, substantial excursion at joints of the lower body is required. Previous research has demonstrated that restriction in ankle joint dorsiflexion range of motion (ROM) is associated with increased stress experienced at the knee and lower back. As a consequence, many individuals perform the squat with a wedge located under the heel to position the ankle initially in plantarflexion and thereby enable greater joint excursion during the squatting movement. The purpose of this study was to investigate the associated kinematics and kinetics of the squat performed on a level surface and with heel rises of different heights in participants with and without restricted ankle dorsiflexion.

Methods: Twelve recreationally active males (age: 27±3.9 years; height: 170.7±5.5 cm; mass: 69.7±13.8kg) volunteered to participate in the study. Ankle dorsiflexion ROM was assessed in two positions (knee extension and 30° knee flexion) with the foot moved passively from a neutral position until resistance was noted. If the ROM was found to be less than 20° and/or 10° with the knee in full extension or 30° of flexion, respectively, the participant was classified as exhibiting restricted ankle dorsiflexion. Six of the twelve participants were subsequently identified as exhibiting restricted ankle dorsiflexion. Therefore, the participants were sectioned into two groups each comprising six individuals.

All squats were performed with a bar of negligible mass positioned across the upper trapezius. Three dimensional kinematics and kinetics of the ankle and knee were quantified using inverse dynamics in a motion analysis laboratory, with models processed using Vicon Nexus 1.8.5 software (Oxford Metrics, Oxford, UK). Each participant performed squats barefoot under five different conditions, including: 1) level surface, 2) 1.5cm heel rise, 3) 2cm heel rise, 4) 2.5cm heel rise and 5) 3cm heel rise. For each condition, participants performed six repetitions of the squat under a set cadence with the average value over the six repetitions selected for further analysis. Data were analysed using a mixed between-within factorial ANOVA (group × 2, heel height × 5).

Results: No significant interaction effects were noted between group and heel height for peak ankle dorsiflexion and knee joint ROM ($p=0.73$ and $p=0.98$, respectively). A significant main effect of heel wedge height was noted for peak ankle dorsiflexion ($p<0.01$). No significant interaction effects were noted between group and heel height for ankle and knee kinetics ($p=0.31$ to $p=0.81$). Significant main effects were obtained for heel wedge condition on knee medio-lateral shear forces ($p=0.03$) and knee compressive forces ($p<0.01$). The results showed that knee joint forces increased with greater heel elevations. In addition, a significant group main effect was obtained for compressive forces at the knee ($p<0.001$),

with larger forces experienced by the group with restricted ankle dorsiflexion. Finally, ankle antero-posterior shear forces were found to increase with greater heel elevations for both groups of participants (p=0.01).

Conclusion: The results of the study demonstrate that the use of a wedge underneath the foot to raise the heel can cause a number of biomechanical changes in individuals with and without limited dorsiflexion ROM when performing the squat. In particular, the results demonstrate that the use of heel wedges decreases peak dorsiflexion as the ankle is placed in an initial plantarflexed position and joint excursion remains relatively constant. In contrast, the results of the study demonstrate that the use of heel wedges significantly increase various forces experienced at the ankle and knee joint, with larger force values measured with greater heel elevation. Coaches and clinicians should be aware of these changes, particularly with individuals in a rehabilitation setting where increased skeletal forces may be of practical significance.

Table:

Variable	Restricted Dorsiflexion			Non-restricted Dorsiflexion		
	Level	HW (2cm)	HW4 (3cm)	Level	HW (2cm)	HW4 (3cm)
Peak dorsiflexion(°)	34.1±7	28.8±8	23.9±6	34.4±6	29.5±6	28.5±6
Knee ROM(°)	117±4	125±6	125±5	120±6	122±8	126±10
Ankle AP force (N)	13±5	20±5	26±11	10±2	17±4	24±12
Knee ML force (N)	16±9	28.4±26	22±19	15±2	21±12	17±9
Knee COMP force (N)	133±8	252±31	362±25	122±10	220±16	337±26

HW = heel wedge, AP = antero-posterior, ML = medio-lateral, COMP = compressive.

PO-0344

COMFORT ASSESSMENT IN BIKE FITTING

Jose Ignacio Priego [1,*] Angel Gabriel Lucas-Cuevas [2] Rosario Salvador-Palmer [1] Pedro Pérez-Soriano [2] Rosa Mª Cibrián Ortiz de Anda [1]

[1]Department of Physiology, [2]Department of Physical Education and Sports, University of Valencia, Valencia, Spain

Introduction and Objectives: Comfort has a strong effect on injury prevention and enhancement of performance in different sports. However, it is still unclear how different postures may influence the cyclist's perception of comfort on the bike during cycling. Furthermore, an adequate posture in cycling is essential to improve performance and reduce the risk to suffer an overuse injury [1]. The aim of the study was therefore to assess the influence of different positions on the bike on the perception of comfort during cycling.

Methods: Twenty participants (30.9 ± 11.1 years, 75.5 ± 9.9 kg, 178.5 ± 6.8 cm, 207 ± 133 km/week) completed one pre-test and three main tests. The pre-test consisted of an incremental cycling test to exhaustion using a stationary cycle ergometer in order to determine the individual workload for each participant. The three mains tests consisted of 45 minutes of cycling at 90 rpm at their individual 50% peak power output. Each test was performed with a different knee flexion angle (20º [Knee20º], 30º [Knee30º], 40º [Knee40º] when the pedal crank was at 180º) and trunk flexion angle (35º [Trunk35º], 45º [Trunk45º], 55º [Trunk55º] with respect to the transverse plane). Angles were measured using 2D motion analysis during cycling. Knee angle was defined as the degrees of knee flexion with respect to the anatomical reference position (static upright standing posture) considered zero degrees [2]. Perception of comfort of the limbs and of the trunk was reported one minute before the end of each test using a 5-point Likert scale ranging from very uncomfortable (-2) to very comfortable (+2). A repeated measures ANOVA was used to examine the difference in trunk and limb comfort between the different postures.

Results: Knee30º was significantly perceived as the most comfortable posture of the limbs (with scores between "neither comfortable nor uncomfortable" and "very comfortable"). Knee20º was reported to be "neither comfortable nor uncomfortable" ($p=0.1$, 95%CI [-0.5, 0.6]). This position was considered more comfortable than Knee40º (95%CI [-1.7, -0.9], ES=1.36 and $p<0.01$) but more uncomfortable than Knee30º (95%CI [0.6, 1.5], ES=0.94 and $p<0.01$). Knee40º was perceived the most uncomfortable posture of the limbs (with scores between "neither comfortable nor uncomfortable" and "very uncomfortable"). Knee fitting significantly affected trunk comfort, Knee30º (x=0.9, 95%CI [0.5, 1.3]) was considered more comfortable for the trunk than Knee40º (x=0.1, 95%CI [-0.4, 0.6], ES= 0.83 and $p=0.03$).

Trunk55º (x=1.0, 95%CI [0.6, 1.4]) was considered more comfortable than the most flexed position Trunk35º (x=0.0, 95%CI [-0.5, 0.5], ES= 1.1 and $p<0.01$). Trunk position did not have any effect on limb comfort.

Conclusion: The main findings in our study were that cyclists perceived the limb intermediate flexion posture (30º of knee flexion) and the trunk in the most upright position (55º of trunk flexion) as the most comfortable postures. Also, the posture with the highest knee flexion (40º) was perceived as the most uncomfortable and it also produced discomfort in the trunk. A knee flexion angle of 25º to 30º when the pedal crank is at 180º during static assessment has been recommended to prevent overuse injuries and improve performance [1]. However, Ferrer-Roca et al. [3] also suggested that during dynamic

assessment, the recommended range of knee flexion angle is between 30º to 40º, but with absolute values and without static correction. The limb postures that were within the recommended flexion range (Knee30º) and outside of this range (Knee40º) with the static correction [2] and in absolute angle values (39.8± 4.0º and 50.4 ±3.5º, respectively) [3], were considered the most comfortable and uncomfortable postures, respectively. The saddle position with the highest knee flexion (40º) resulted in greater trunk discomfort. This result showed that the posture of the limbs affects the perception of trunk comfort due to changes in the hip flexion angle during exercise. This interaction between the pelvic and the spine is in agreement with a previous study [4]. Finally, an upright position was perceived more comfortable than a position where the trunk is flexed forward. This should be taken into account depending on cycling purpose. For recreational cycling, the upright position is recommended in order to improve comfort as shown in the present study. For competitive cycling, on the other hand, a more flexed position is recommended in order to decrease air resistance and improve speed. In conclusion, cyclists' perception of comfort on the bike should be taken into account when it comes to choosing the most beneficial position since it can play a major role when aiming to enhance performance and reduce injury occurrence in cycling.

UPPER BODY POWER AND FLEXIBILITY AFFECT RUNNING THROW-IN PERFORMANCE IN YOUNG FOOTBALL PLAYERS

Dale Azzopardi [1] Susan Dewhurst [1] Theodoros Bampouras [1,*]

[1] Medical and Sport Sciences, University of Cumbria, Lancaster, United Kingdom

Introduction and Objectives: Throwing performance is crucial to success in many sports and a considerable amount of literature has been published with regard to overarm throwing performance [1]. The two-handed overhead throw, used in football, has received little attention, however, despite its importance to the gameas throw-ins contributed to 4% of the goals scored in the 2006 FIFA World Cup [2]. The literature that is available around throw-ins reveals that power has been the main component of interest [3]. Moreover, studies to date have only focused on the upper-body and therefore the extent that other factors could contribute to throw-in performance such as leg power or flexibility are not known. In addition, the scarce literature on football throw-in examines the adult population while studies on youth populations are even fewer, despite the established different physical demands between the two age groups. The aim of the current study was to determine the relationship between maximum throwing distance and height, shoulder flexibility, upper- and lower-body power in youth team football players. It was intended that the results will provide information to help coaches design appropriate and effective training programmes for increasing football throw-in distance.

Methods: With Instituitnal Ethics approval, thirty-nine male youth team football players volunteered for the study (age 16.6 ± 0.9 years; height 1.74 ± 0.06 m; body mass 71.3 ± 13.4 kg). All participants had a minimum of 3 years competitive playing experience, were currently playing for a football club and familiar with taking football throw-ins. Goalkeepers were excluded from the study as they typically do not perform this skill. A running throw-in was performed indoors using a FIFA approved football. The running distance was standardised and within the distances allowed by football pitch restrictions. Height was measured according to the ISAK protocol. Shoulder flexion was measured using video analysis. Upper-body power was assessed using a 3 kg medicine ball seated chest pass while lower-body power was assessed from a countermovement jump without arm swing. For both throw-ins and measurement variables, two trials were performed and the best performance was used for further analysis. Following examination of data multicollinearity and residuals' homoscedasticity, correlation and distribution normality a hierarchical multiple regression was used to examine the variables that would better predict running throw-in distance.

Results: Mean results for running throw-in distance was 18.91m ± 3.47 while shoulder flexion, upper-body power , and lower-body power results were 181.68 ± 6.16 º, 3.97 ± 0.38 m,and 3377.8 ± 613.5 W, respectively. The regression model indicated that the only significant predictors of throw-in distance were upper-body power ($p < 0.001$, adjusted $R^2 = 0.373$) and flexibility ($p < 0.001$, adjusted $R^2 = 0.637$).Regression coefficients of the measured variables can be found in Table 1.

Conclusion: The results indicate that upper-body power and shoulder flexibility are the major contributors to running throw-in performance in younger football athletes form the variables used in the current study. Their impact, although moderate, could be sufficient in achieving true performance changes . Youth coaches should consider these results when designing training programmes for younger athletes rather than following suggestions based on studies for adults, as well

assist them in throw in tactics. In addition, future studies should attempt to examine additional factors that could contribute to running throw in performances.

Table:

	B	SE B	β
Constant	-41.977	15.179	
Lower body power	-0.001	0.001	-0.136
Upper body power	4.908	1.081	0.577*
Flexibility	0.306	0.064	0.523*
Height	-0.066	0.056	-0.126

Caption: Coefficients the regression model. The order of the variables in the table reflects the entry order to the model.

THE SIX-WEEK SWISS BALL TRAINING AND DETRAINING EFFECT ON FUNCTIONAL PERFORMANCE FOR HIGH SCHOOL BADMINTON PLAYERS

Chung-Lin Wu [1,*] Chen-Fu Huang [2] Min-Hao Hung [2]

[1]Biomechanics Laboratory, Department of Physical Education NTNU, NEW TAIPEI CITY, Taiwan, Republic of China, [2]Department of Physical Education NTNU, NEW TAIPEI CITY, -

Introduction and Objectives: Swiss ball trainingwas applied as rehabilitation therapy for a long time, and now has been widely used in physical fitness and sports training. The principle of Swiss ball training is to balance body on an unstable surface in order to achieve better proprioception, balanceperformance and muscle coordination(Fuller, 2002; Robert, Peter, & Brendan,2004).Many studies stated that Swiss ball is a good tool for training or rehabilitation equipment. Recent studies found that incorporating of short-term Swiss ball training into the abdominal training program was more effective than general resistance training. (Cosio-Lima,Reynolds, Winter, Paolone, & Jones, 2003). Previous researches have proved the effects of Swiss ball training on sports performance, but the studies did not put emphasis on the maintaining effect. The purpose of this study was to determinate the training and detraining effect on functional performance in high school badminton players while 6-weeks Swiss ball training performed.. The purpose of this study was to determinate the training and detraining effect on functional performance in high school badminton players while 6-week Swiss ball training performed. The functional performance assessments were carried out before, immediately after 6-weeks training, and after the 6-weeks of training termination.

KEYWORDS: instability training, dynamic balance, footwork, non-dominant leg

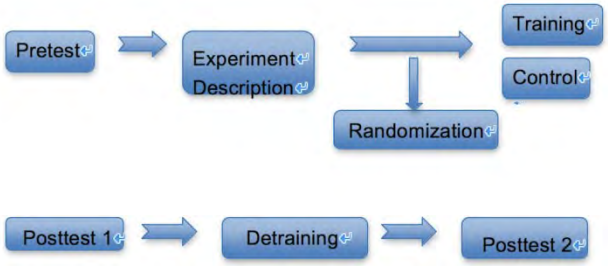
Methods: Sixteen high school badminton players with experience of three years or more were participated in this study. Those subjects were randomly divided into control(n=8,age=16.63±0.48years,height=172±3.24cm,weight=68.13±3.06kg)and training group(n=8,age=16.880.78years,height=172.75±4.58cm ,weight=63.5±3.20kg).

The functional performance, including distance of standing long jump, height of vertical jump,dynamic balance, and timed left-to-right footwork and timed diagonal step footwork, were measured before, after6 weeks of trainingimmediately, and after the 6-weeks of training termination. Then the training group received Swiss ball training, which has contains eight movements of trunk, four of lower limbs training, and one of balance training, twice a week for 6-week. After 6-week training, the training group terminated Swiss ball training for another 6-week, and then reassessed the functional performance. The repeated-measures ANOVA were used to analyze the functional performance variables between two groups for three time assessments.

Results: The left-to-right footwork and dominant leg dynamic balance instantly after training was better thanbeginning and reached significant difference($P<0.05$). The dynamic balance performance of non-dominant leg instantly after training was thebest ($P<0.05$). The performance of long jump and vertical jump after detraining for 6-week was better than the time

after training and reached significant difference(P<0.05). The times diagonal footwork was the best performance in the detraining. Others functional performance was not statistically significant differences.

Figure:



Conclusion: The 6-week Swiss ball training could contribute to left-to-right footwork and the dominant leg dynamic balance. For both training group and control group were not statistically significant difference, it was maybeless numbers of participants andthe shorter length of training period. We suggested that the future research wouldfocus on more training periods to understand appropriated training effect.According to the results of this study, we suggested that Swiss ball training could be brought into conditioning and power phase to enhance the some functional performance of badminton player.

A BIOMECHANICAL INVESTIGATION OF THE USE OF THE STRETCH SHORTENING CYCLE WHEN PERFORMING THE KETTLEBELL SWING

Paul Swinton [1,*] Deborah Jason [1]

[1]School of Health Sciences, Robert Gordon University, Aberdeen, United Kingdom

Introduction and Objectives: Kettlebell training has gained popularity over the last decade as a form of resistance training. A small number of studies have recently investigated the acute physiological and biomechanical effects created when performing kettlebell exercises. Research has demonstrated that the kettlebell swing, the most commonly performed kettlebell exercise, results in large force and power outputs and therefore it is suggested that repeated bouts of the exercise has the potential to chronically improve strength and muscular power. The kettlebell swing comprises rhythmic phases where the kettlebell and body mass are lowered under control and then rapidly elevated. This phasic movement pattern is common in sporting actions such as running and jumping where the presence of a phenomenon referred to as the stretch shortening cycle describes the storage of elastic energy during the lowering phase and subsequent release of the stored energy during the elevation phase. Exercises that prominently feature the stretch shortening cycle are frequently included in the power training of athletes. Therefore, the purpose of the present study was to investigate the extent to which the stretch shortening cycle phenomena featured during performance of the kettlebell swing.
Methods: Six male and three female recreationally trained participants with a minimum of six months experience performing the kettlebell swing were recruited for this study. Participants performed kettlebell swings with, and without a lowering phase. For each condition, the participants performed six repetitions with a 16 kg and 24 kg kettlebell. The condition with a lowering phase replicated standard practice and six repetitions were performed continuously. In contrast, swings performed without a lowering phase were initiated with the kettlebell resting on a wooden box with the participant adopting the same posture used in the other condition. Repetitions performed without a lowering phase were interspersed with a ten second rest period to ensure the effects of the stretch shortening cycle did not influence the subsequent elevation phase. Three dimensional kinematics and kinetics of the ankle knee and hip were quantified using inverse dynamics in a motion analysis laboratory, with models processed using Vicon Nexus 1.8.5 software (Oxford Metrics, Oxford, UK). A repeated measures ANOVA with two within factors (load * condition) was used to test for differences.
Results: To assess the effects of the stretch shortening cycle, the primary variable utilised was peak joint power summed at the hip, knee and ankle. A significant main effect of load ($p<0.01$) and condition ($p<0.01$) was obtained (Table 1). The results demonstrated that the inclusion of a lowering phase increased peak joint power by 45% and 17% during swings performed with the 16 and 24kg load, respectively. A significant main effect of load ($p<0.01$) and condition ($p<0.01$) was also observed for the peak joint force experienced at the hip (Table 1). The results also demonstrated larger forces experienced for the heavier load and when the movement was performed with a lowering phase.
Conclusion: The results of the present study demonstrate that the stretch shortening cycle features prominently during performance of the kettlebell swing. Increases in peak joint power of up to 45% were noted between the movement performed with and without a lowering phase. In addition, the differential for force measured at the hip joint was even

larger, with a 110% increase in force measured for the heaviest kettlebell load when including a lowering phase. The results of the study provide further evidence that the kettlebell swing is likely to produce a mechanical stimulus that is closely aligned with the power training goals of athletes.

Table:

Load/Condition	Peak Joint Power (W.kg)	Peak Hip Force (N.kg)
16 kg - lowering phase	46.0±15.7	54.5±71.3
16 kg + lowering phase	66.5±15.1	76.9±99.71
24 kg - lowering phase	71.3±24.4	78.7±126.3
24 kg + lowering phase	83.7±24.02	165.3±65.7

BIOMECHANICAL COMPARISON OF LONG HEAD OF BICEPS TENODESIS WITH KNOTLESS SCREW AND INTERFERENCE SCREW TECHNIQUES

Wei-Ren Su [1,*] Chih-Hsun Chang [2] Florence Y Ling [3] Chih-Kai Hong [2] I-Ming Jou [1]

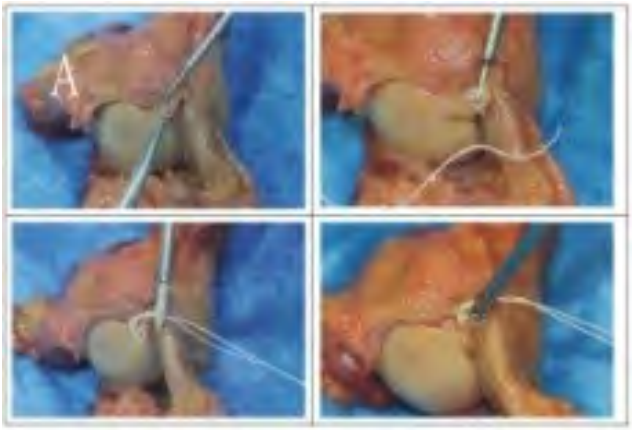
[1]Orthopaedic Surgery, National Cheng Kung University Hospital, [2]Department of Medicine, National Cheng Kung University College of Medicine, Tainan, Taiwan, Republic of China, [3]University of Texas Health Science Center at San Antonio School of Medicine, San Antonio, United States

Introduction and Objectives: The purpose of this study was to biomechanically evaluate a new technique of knotless screw fixation for suprapectoral biceps tenodesis and to compare it with the interference screw fixation[1,2].

Methods: Twenty-four fresh-frozen human cadaveric shoulders with a mean age of 63.3±8 years were studied. The specimens were randomly divided into 3 experimental biceps tenodesis groups (n=8): single knotless screw, double knotless screw and interference screw (Figure). Each tenodesis specimen was mounted on a mechanical testing machine, preloaded for 2 minutes at 5 N, and followed by a test of axial load to failure (1 mm/s). We evaluated the mode of failure and computed the ultimate failure load and stiffness.

Results: The interference screw group had the highest ultimate failure load (215.8±43.1 N), significantly higher than that for the single (70.1±13.6 N) and double (148.8±13.1 N) knotless screw groups ($P < .0001$). In addition, the interference screw group had the greatest stiffness (25.7±5.2 N/mm), significantly higher than that for the single (7.1±1.5 N/mm) and double (11.9±1.9 N/mm) knotless screw groups ($P < .0001$). The double knotless screw group had the second greatest ultimate failure load and stiffness, significantly greater than that of the single knotless screw technique ($P < .0001$ and $P = 0.024$, respectively) (Table). The most common mode of failure was suture slippage for both the single (6/8) and double knotless screw (7/8) groups and biceps tendon tearing for the interference screw groups (6/8).

Figure:



Suprapectoral tenodesis with single Footprint PK anchor (Smith & Nephew) on a right proximal humerus.

Conclusion: In this biomechanical study, double knotless screw fixation was found to have a significantly greater ultimate failure load and stiffness than the single knotless screw fixation, but values lesser than the interference screw fixation.

Table:

Table : Results for All Testing Parameters			
	Single Knotless Screw	Double Knotless Screw	Interference Screw
Age (yr)	68±8	66±5	65±11
BMD (g/cm^2)	0.73±0.17	0.68±0.16	0.72±0.13
Failure Load (N)	70.1±13.6 *P*< 0.0001	148.8±13.1 *P*= 0.0002	215.8±43.1
Stiffness (N/mm)	7.1±1.5 *P*< 0.0001	11.9±1.9 *P*< 0.0001	25.7±5.2
NOTE. P values are presented for comparison between interference screw and the other 2 knotless screw techniques.			
BMD, bone mineral density.

PO-0349

A FOOT MORPHOLOGY-RELATED LOADING CHARACTER OF HABITUALLY UNSHOD AND SHOD RUNNERS

Qichang Mei [1,*] Lin Yu [1] Julien Baker [2] Ukadike Ugbolue [2] Yaodong Gu [1]

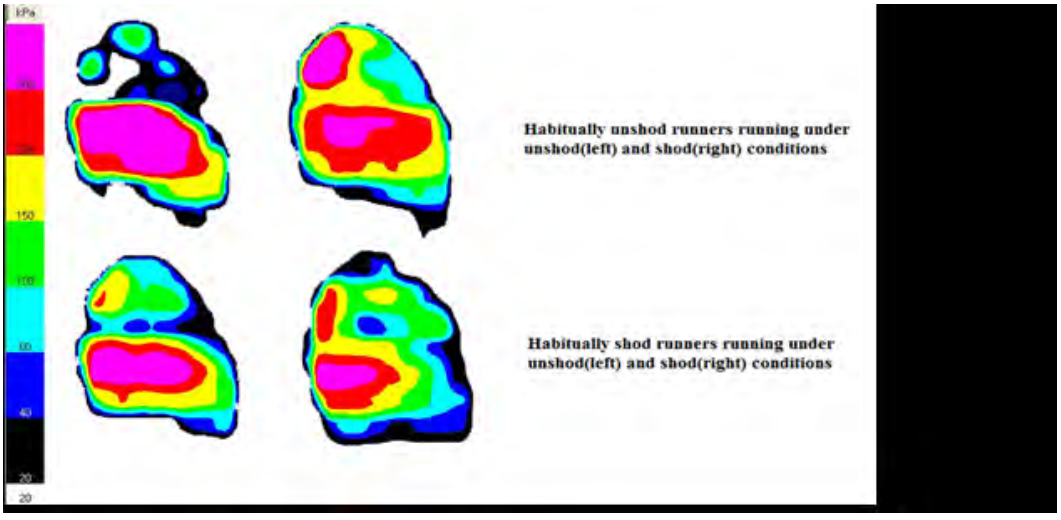
[1]Faculty of Sports Science, Ningbo University, Ningbo, China, [2]School of Science and Sport, University of the West of Scotland, Hamilton, Lanarkshire, Scotland, United Kingdom

Introduction and Objectives: Feet morphological characteristics have been proven to be closely linked with ethnicities (Hoffmann, 1905). One unique difference between habitually unshod running feet and shod running feet is that the great toes of habitually unshod runners are quite separate from the other toes compared with habitually shod runners. It is aimed in this study to investigate the separate hallux's function of habitually unshod runners and shod runners while running under shod and unshod conditions.

Methods: A total of eighteen habitually male barefoot (Indian) runners and twenty habitually male shod (Chinese) runners participated in the running test. Each participant conducted six trials of running test with the speed of 3.0±0.2m/s. The in-shoe plantar pressure measurement system (Novel Pedar-X System, Germany) was employed to measure the pressure and force exerted on the pressure sensors of the insole, and the insole was divided into eight anatomical parts, including medial rearfoot (MR), lateral rearfoot (LR), medial midfoot (MM),lateral midfoot (LM), medial forefoot(MF), lateral forefoot(LF), hallux (H) and other toes (OT). The peak pressure, contact area and force time integral were collected to analyze the difference while pushing off between habitually unshod feet and shod feet.

Results: Under unshod condition, the peak pressure and force time integral in the medial forefoot and lateral forefoot parts of habitually unshod and shod runners' running are significantly larger than those under shod conditions. However, the peak pressure and force time integral in the hallux part of habitually unshod runners' shod running are significantly larger than that under unshod condition. And the peak pressure and force time integral in the medial and lateral forefoot parts are significantly reduced compared with those of unshod conditions. The figure shoes the peak pressure in the forefoot and toes part while pushing off.

Figure:



Conclusion: The increased peak pressure and force time integral in the hallux part of habitually unshod runners under shod condition could be explained with the hallux's prehensile function like fingers (Lambrundi, 1932). While shod running, the separate hallux of habitually unshod runners could grip the ground in the pushing off phase. Owing the gripping function of hallux, the loading to the forefoot was correspondingly reduced, thus lowering the risks of injuries to the forefoot (metatarsal) part. Conclusions and Disclosure The separate hallux shared parts of foot loading and reduces the loading focused in the forefoot region during push-off phase under shod condition. It will be beneficial for the prevention of feet injuries like plantar fasciitis and metatarsal stressed fracture.

PO-0350

DO SUCCESSIVE JUDO MATCHES PROVOKE DECLINE IN LOWER-LIMB MUSCLE POWER?

Daniele Detanico [1,*] Saray Giovana dos Santos [1]

[1] Physical Education Departament, Federal University of Santa Catarina, Florianópolis, Brazil

Introduction and Objectives: Muscle strength is considered potential predictor of judo performance, since high muscle power is required mainly for the execution of throwing techniques [1]. Thus, considering that judo players performed several matches during a tournament day with a minimum recovery [2], this study aimed to investigate the acute effects of successive judo matches on lower-limb muscle power.

Methods: Twenty male judo athletes (20.7 ± 4.6 years old; 72.8 ± 12.6 kg; 174.0 ± 8.7 cm; 13.9 ± 3.1% of body fat) volunteered to participate in this study. All athletes participated in several national and state tournaments and were regularly training 3–4 times a week during the evaluation period. Judo athletes performed three 5-minute judo matches with 15 minutes interval of passive rest among the matches. Before the first match and after each match the athletes performed three maximal countermovement jumps (CMJs) on a piezoelectric force platform (Quattro Jump, model 9290AD, Winterthur, Switzerland) at a frequency of 500 Hz in order to analyse the lower-limb muscle power. Analysis of variance for repeated measures (within-subjects ANOVA) and Bonferroni post-hoc tests were used to compare the CMJ performance among the matches.

Results: Table 1 shows the jump height and power output of CMJ in pre-match and post-match 1, 2 and 3. According to the analysis of variance, jump height showed significant reduction in post-match 2 when compared to the baseline and post-match 1. Similarly, the jump height in post-match 3 decreased when compared to the baseline and post-match 1. No significant effect of power output was detected in the matches. The simulated judo matches induced fatigue in the lower limbs, as indicated by the decline in CMJ height (3.6% after match 2 and 3.2% after match 3 when compared to baseline). This finding may be explained by the high eccentric-concentric load (SSC) in the actions performed by the lower limbs during the judo-specific techniques. It has been documented that prolonged and intense eccentric exercise, mainly involving SSC, induces immediate and prolonged reductions of function in several muscles, such as stretch-reflex sensitivity, joint stiffness regulation and jump performance [3].

Conclusion: We conclude that three successive judo matches induced fatigue in lower limbs. These findings may provide important information for coaches and physical trainers to delineate specific training to improve physical performance. It is recommended that the training design should be directed to power-specific resistance training in the lower limbs, aiming to maintain optimum levels of neuromuscular performance during successive judo matches.

Table:

	Pre-match	Post-match 1	Post-match 2	Post-match 3
H (cm)	45.38 ± 5.24	44.96 ± 5.56	43.74 ± 5.81*#	43.93 ± 6.13*#
P ($W.kg^{-1}$)	27.73 ± 3.92	27.89 ± 3.63	27.50 ± 4.40	27.39 ± 3.94
Data are expressed as mean ± standard deviation; H: jump height; P: power output. *Significantly different from pre-match ($p<0.05$). # Significantly different from post-match 1 ($p<0.05$).

PO-0351

ACUTE EFFECT OF KINESIO TAPE ON KNEE JOINT BIOMECHANICS DURING SIDESTEP CUTTING TASK

Chuanpis Boonkerd [1,*] Weerawat Limroongreungrat [1] Jos Vanrenterghem [2]

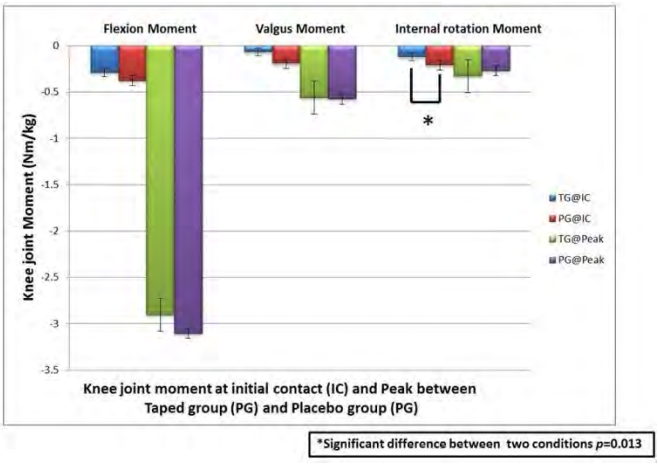
[1]College of Sports Science and Technology, Mahidol University, Nakronpathom, Thailand, [2]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: Kinesio tape (KT) has been widely used for different purposes including structural support, reducing swelling and inflammation, stimulating and inhibiting muscle activity, and improving blood and lymph flow [1]. Anterior cruciate ligament (ACL) injury commonly occurs during non-contact situations particularly during deceleration, sidestep cutting and landing [2]. KT has also been used to support the knee after ACL injury to prevent tibial translation. It is believed that KT allows more functional activity as compared to other types of support such as functional knee braces and prophylactic tape. However, no previous studies have investigated the effect of KT on knee joint motion during sidestep cutting tasks. Therefore, the purpose of this study was to investigate the acute effect of KT on knee joint motion during sidestep cutting task.

Methods: Five healthy males (age 21 ± 0.9 years; weight 69 ± 8.5 kg; height 1.7 ± 0.8 m) volunteered in the study. Subjects performed sidestep cutting tasks at 45 ± 5° of approach direction with running speed at 4.5 ± 0.5 $m \cdot s^{-1}$. A 10 camera motion analysis system (BTS Bioengineering, Italy) synchronized with force plate (Piezoelectric pressure sensors, Kistler, Switzerland) were used to record kinematics and kinetics. The LJMU lower limb and trunk model was applied [3]. Each subject was randomly tested two times; 1) with a standardized KT technique for ACL injury (Taping group: TG) and 2) with the same tape and technique but without tension (Placebo group: PG). Three trials per condition were averaged and analyzed. Knee joint angles and moments from initial contact (IC) to the first 100 milliseconds of foot contact were analyzed using Visual3D software (C-motion, Inc., USA). Multiple t-tests were performed with Bonferroni correction adjustment of the alpha level by dividing the conventional alpha of 0.05 by the number of t tests.

Results: No significant differences of knee joint angles between TG and PG were found (Table 1). For knee moments, only internal rotation at IC between was found significant difference (Fig. 1).

Figure:



Conclusion: Although the results did not show significant differences between the two conditions, the TG had smaller peak knee flexion and valgus angles which may indicate that the tape tension provide some support for joint stability. However, whether the tape is strong enough to help prevent ACL injury, it is still questionable since knee flexion and valgus moments were similar in both conditions. Nevertheless, further research with a large sample size is warranted to clarify the beneficial effect of KT on movement control.

Table:

Knee joint angles at the initial contact (IC) and peak knee joint angles during sidestep cutting task

Angle (◦)	TG (N=5)Mean±SEM	PG (N=5)Mean±SEM	*p*-value
Knee flexion at IC	23.9±1.90	23.6±2.73	0.94
Knee valgus at IC	-2.2±1.07	-3.9±0.67	0.23
Internal rotation at IC	4.4± .25	5.2±1.71	0.68
Peak knee flexion	45.2±2.28	49.6±2.23	0.12
Peak knee valgus	-5.5±1.20	-7.6±1.45	0.20
Peak knee internal rotation	14.0±0.96	15.71±5.20	0.11

CENTER OF PRESSURE VELOCITY DURING TRUNK MOTION ARE ASSOCIATED WITH PERFORMANCE IN WHEELCHAIR RUGBY-SPECIFIC SKILLS

Thiago Lemos [1,*] Jeter Freitas [1] Miriam Mainenti [1 2] Patrícia Vigário [1]

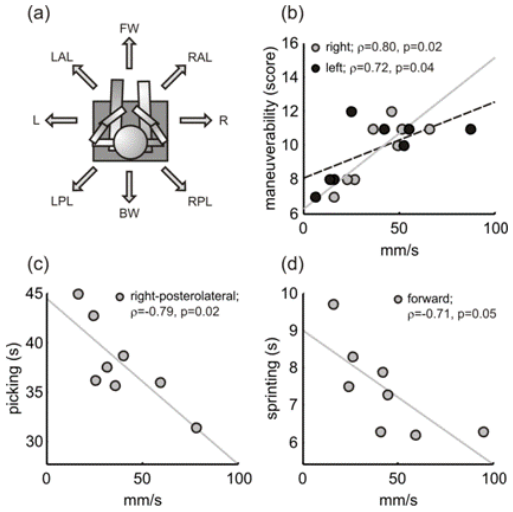
[1]Graduate Program in Rehabilitation Sciences, UNISUAM, [2]Escola de Educação Física do Exército, Rio de Janeiro, Brazil

Introduction and Objectives: The aim of the present study was to investigate the relationship between trunk stability measures and the performance in sport-specific skills in wheelchair rugby players.

Methods: Eight male subjects were recruited from a local wheelchair rugby team of the main division of the Brazilian wheelchair rugby championship. Seven subjects had spinal cord injuries at the level of C5-C7, and one had Guillain-Barre syndrome. All subjects provided their own International Wheelchair Rugby Federation classification. The classification scores were 0.5 (n=2), 2.0 (n=1), 2.5 (n=4) and 3.5 (n=1). The Beck Battery of Quad Rugby Skills Tests was employed to assess sports-specific skills performance (pass for accuracy; pass for distance; maneuverability with the ball; picking and sprinting). The tests took place at the same court used for athlete's training, and each subject used his own rugby wheelchair. For trunk motion assessment the subjects were placed in a sitting position on a force platform embedded in a stiff wooden block, with their feet unsupported. They were asked to lean the body in a selected direction, indicated by dot markers separated by 45 degrees interval from each other (Fig. 1a). The subjects should lean as far as they could and return to the initial position, in a comfortable self-selected speed. The center of pressure (COP) coordinates were measured with a force platform (AccuSwayPLUS, AMTI) sampled at 100Hz and low-pass filtered at 10Hz. The average velocity of COP displacement was computed. Spearman correlation (rho) analysis was applied to investigate the relationship among the results of the Beck Battery tests and COP velocity in the different directions.

Results: COP average velocity during trunk motion showed strong association with performance in the Beck Battery tests. Specifically, skill of maneuvering with the ball was associated with faster lateral COP motion (right and left motion, Fig. 1b). Also, faster right-posterolateral and forward COP displacement were correlated with performance in picking and sprinting tests, respectively (Fig. 1c and 1d). Finally, there was trend to perform better in the pass for distance test when subject showed a higher COP average velocity during backward motion (rho=0.70, p=0.06).

Figure:



Caption: Fig 1. (a) Schematic illustration of the experimental procedures indicating the eight directions in which subjects must lean their body during trunk motion trials. Directions were assigned in a clockwise orientation as: FW, forward; RAL, right-anterolateral; R, right; RPL, right-posterolateral; BW, backward; LPL, left-posterolateral; L, left; LAL; left-anterolateral. Spearman correlation coefficient (rho) and the corresponding p-values (indicated as inset in the panels) showed a strong association between COP average velocity in a particular direction (also indicated as inset) and performance in the maneuverability with the ball (b), picking (c) and sprinting (b) tests. Least-squares regression lines are shown to emphasize the relationship between postural and sports skills performance.

Conclusion: Faster trunk motion in specific directions was correlated performance in locomotor/sport specific-related skills in wheelchair rugby players. Seated postural stability measures, in particular those related with the velocity of trunk motion, should be considered for sports classification and for monitoring of the training status of wheelchair rugby players.

PO-0353

AGE-RELATED DIFFERENCES IN LOWER EXTREMITY MECHANICS DURING RUNNING

Mariana Souza [1,*] Ana Flávia Dos Santos [1] Bruna Luz [1] Jéssica Souza [1] Theresa Nakagawa [1] Fábio Serrão [1]

[1] Physiotherapy Department, Federal University of Sao Carlos, Sao Carlos, Brazil

Introduction and Objectives: The increase in life expectancy and the benefits that physical activity brings to health resulted in an increase in middle-aged and elderly individuals who practice run[1]. However, studies show that the incidence of injury in older individuals is higher than in young individuals[2]. In addition, older runners take longer time to recover from an injury and thus, take more time to return to practice physical activities[3]. This higher incidence may be partly due to changes in the running kinematics[4]. However, there are few studies evaluating the effect of aging on the kinematics of the lower limbs and comparing young, middle-aged and elderly runners. The aim of this study was to evaluate the kinematics of the hip and knee in young, middle-aged and elderly runners at touchdown in the fontal plane during running on a treadmill to have a better understanding of the biomechanical changes that occur due the aging process.

Methods: Twelve subjects were separated into three groups. Group 1 (H1) included four men aged between 18 and 35, group 2 (H2), with four men aged between 36 and 60 years and Group 3 (H3), with four men aged over 61 years. As inclusion criteria, the subjects should run more than 16 kilometers per week and be a rearfoot striker during running[5]. The exclusion criteria were any incidences of injury in the three months prior to the experiment, and musculoskeletal alterations in the lower limbs that could affect the running biomechanics[6]. Kinematic evaluation was performed during 5 minutes running on a treadmill using Qualisys Motion Capture System (Qualisys Medical AB, Sweden) with six cameras and a sampling frequency of 240Hz. At least five consecutive steps were recorded for analysis of knee and hip angle at touchdown in the frontal plane. The data were smoothed with a 12Hz low-pass Butterworth filter of fourth order and zero lag. One-way ANOVA test was performed to comparison between groups and *post hoc* comparisons were performed using Bonferroni adjustments ($\alpha = 0,05$).

Results: Significant differences were found for knee abduction between H1 and H2 (higher values for H2, $p = 0.012$) and between the H1 and H3 (higher values for H3, $p = 0.007$). In addition, significant differences were found for hip adduction between H1 and H2 (higher values for H2, $p = 0.007$) and H1 and H3 (higher values for H3, $p = 0.032$). There were no significant differences between groups H2 and H3 for the variables evaluated. Studies have shown that an increase of hip adduction and knee abduction is associated with an increase in the quadriceps angle (Q angle) and this contributes to dynamics knee valgus[7]. As the Q angle reflects the frontal plane forces acting on the patella, kinematic changes of the lower limb in the frontal plane may affect the patellofemoral joint[7]. Thus, excessive knee valgus resulting from hip adduction and/or knee abduction would increase the Q-angle as the patella would be displaced medially[7]. Therefore, there is an increase in the lateral forces acting on the patella, which can lead to a maltracking and can result in an increased contact pressure between the lateral facet and the lateral femoral condyle, leading to articular cartilage degradation and pain over time[8].

Conclusion: Therefore, the older runners showed an increase in hip adduction and knee abduction which are risk factors for certain injuries. These kinematic changes can generate an overload, especially in the knee joint, and might predispose these runners to injury.

Table:

Variables	Groups	Mean	Standard Deviation	ANOVA (p-value)	Bonferroni	
	H1	-3.06	3,84		H1-H2	0.012*
Knee Abduction(+)	H2	5.66	2.53	0.004*	H2-H3	1.000
	H3	6.48	3.17		H3-H1	0.007*
	H1	-2.18	3.16		H1-H2	0.007*
Hip Adduction(-)	H2	-14.57	2.8	0.006*	H2-H3	0.998
	H3	-11.69	5.78		H3-H1	0.032*

THE RELATIONSHIP OF RELEASE FACTORS ON THROW DISTANCE OF FEMALE HAMMER THROWERS

Suzanne Konz [1,*]

[1]Kinesiology, Marshall University, Huntington, WV, United States

Introduction and Objectives: Release angle, release height, and velocity at release are the most influential factors on throw distance according to previous research. No literature statistically has investigated the relationship of release factors on throwing distance of female hammer throwers. The aim of this study was to determine relationship of the release factors on throw distance for female hammer throwers.

Methods: The best performances of the top 10 female throwers at the 2014 USA Track and Field Nationals and 2014 USATF CV OTC meet were examined. Video was captured using two 60 Hz cameras. The best throw of each athlete was digitized and analyzed using the Contemplas Motus 10.0.1 motion analysis system.

Results: No correlations between the release factors and the distance thrown existed in the data set. However, the correlation matrix revealed that variables did correlate with other variables. A stepwise linear regression of the release factors indicated that none of the variables can predict distance thrown. A stepwise linear regression of all factors ($p<.000$ $r=.1.00$) indicates that the separation of the feet and hips at release and the vertical position of the hammer at the take-off during Turn 4 are predictors of throw distance.

Conclusion: The lack of a correlation of release factors with throw distance is interesting. Previous research has correlated release angle, release height, and velocity at release with throw distance. The most important of these typically is velocity at release. Correlation of individual factors with each other was present. Even the lack of representation of release factors within the stepwise linear regression is interesting.

PO-0355

THE EFFECT OF CHANGES TO FORCE LOADING DIRECTION ON CERVICAL INTERVERTEBRAL DISC STRESS DISTRIBUTION DURING A RUGBY SCRUM

Eddie J. Bradley [1,*]

[1]Sport, University of Sunderland, Sunderland, United Kingdom

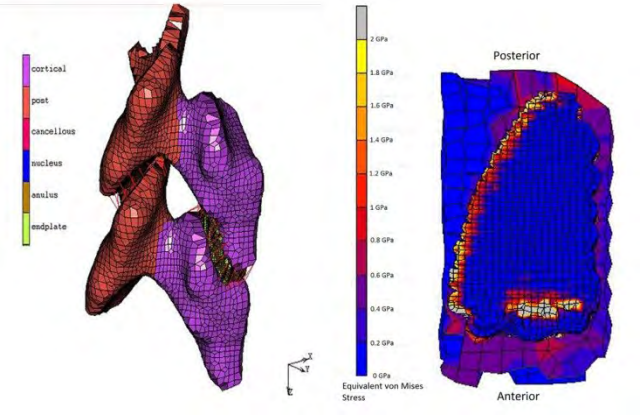
Introduction and Objectives: In rugby union, a front-row player's neck is subjected to repetitive impact forces during scrum engagement. The scrum is one of the most powerful physical encounters in any sport, where up to 9000 N force may be exerted by the pack [1]. The formation of the scrum results in contact between the two opposing front rows. The forces are transmitted through the neck of the front-row players on engagement that occur up to 29 times per game [2]. Berge et al [3] reported early degenerative changes in the cervical region in 47 front-row forwards compared to 48 controls, while Scher [4] found 40 out of 150 rugby players aged 20-35 years displayed signs of osteoarthritic degeneration. Hogan et al [5] identified significant radiographic evidence of degeneration in experienced front-row players compared to non-rugby controls. O'Brien [6] termed this rugby neck, with repeated loading in the scrum identified as the cause. The purpose of this study was to quantify the effect of changes in loading application due to body position adjustments during the scrum on the stress response within a cervical intervertebral disc.

Methods: A finite element model of a C5-C6 cervical spine unit was created (Figure 1 L) with region-specific Young's modulus [7] applied to represent cortical and cancellous bone, endplates, annulus fibrosis and nucleus pulposus. Spinal ligaments and facet joint were modelled as spring elements. Force was applied to the C5 spinous process at nine angles progressing at 5° intervals in the sagittal plane (±20° to a neutral vector perpendicular to the spinal column longitudinal axis). Force application represented contact between the cervical region of one front-row player and the superior shoulder region of the opposing front-row player due to engagement in the scrum, and can be considered as a posterior-anterior directed force vector across the neck in the neutral position with increased superior-inferior force component as the angle varied. Equivalent von Mises stress along the mid-transverse plane of the disc and displacement of the disc were analysed.

Results: In a neutral scrum position (0° loading angle) the maximum equivalent von Mises stress in the intervertebral disc would be 1.7GPa. When the loading angle was altered to +20°, simulating the heads of the front row rising, the maximum stress decreased to 0.78GPa, and increased to 2.48GPa at -20°, with a near linear response (R=-0.988) to the loading angle range. The decrease in the loading angle occurs due to the shoulders of the front-row dropping below the hips, a manoeuvre used by the front row to get underneath the opposite player to gain an advantage. The findings show that this technique is placing the cervical spines of the whole front-row at an increased risk of degenerative injury as it increases the stress within the intervertebral disc. A back slope of 5° [8] produced the best scrummaging performance, which supports the finding that a higher head position is safer and more effective. Distribution of stress throughout the disc was found to be uneven (Figure 1 R), with the maximum stress 3mm from the anterior edge and a secondary peak 2mm from the posterior edge of the disc (Table 1). This agrees with the findings of Panjabi et al. [9], who reported that in the cervical spine the load is borne on the anterior edge of the vertebral body below C4-C5. As the force is transmitted through the

vertebrae, it causes rotation of the superior vertebrae around the facet joint. The disc is compressed anteriorly and the force is transmitted into the disc The distribution of stress in the intervertebral disc may be one of the main causes of disc degeneration reported by Berge [3] and O'Brien [6].

Figure:



Caption: Figure 1. Finite element model of the C5-C6 vertebraal unit with material identification (Left) and Stress distribution in the intervertebral disc after loading at the 0° loading angle

Conclusion: The study indicates the magnitude of the loads that are placed on the cervical spine at different force applications, and repeated exposure may lead to serious injury. These findings may help inform the laws of the game by limiting the body angles of the front row at engagement.

Table:

Angle	-20	-15	-10	-5	0	5	10	15	20
Posterior Peak (GPa)	1.79	1.66	1.53	1.38	1.22	1.22	0.88	0.70	0.51
Anterior Peak (GPa)	2.48	2.32	2.13	1.94	1.72	1.72	1.26	1.02	0.78

PO-0356

THE FATIGUE EFFECT OF SIMULATED FUTSAL MATCH PROTOCOL ON STRENGTH BALANCE OF THE KNEE FLEXORS AND EXTENSORS MUSCLES

Juliano Dal Pupo [1,*] Saray dos Santos [2]

[1]Physical Education Departament, [2]Federal University of Santa Catarina, Florianópolis, Brazil

Introduction and Objectives: Fatigue in team sports is noticeable during a match, reducing the muscles' capacity to generate force. This fatigue effect may causes alterations in the strength balance between knee flexors and extensor muscles [1]; thus, it has been considered as a predisposing factor to muscle strains [2,3]. Thus, the objective of this study was to investigate the fatigue effects induced by a futsal-specific shuttle-run protocol on the conventional concentric quadriceps-to-concentric hamstrings and functional eccentric hamstrings-to-concentric quadriceps torque ratios.
Methods: Twenty-one under-17 and under-20 male futsal players (age = 17.2 ± 1.0 years; body mass = 68.2 ± 4.5 kg; height = 1.75 ± 0.05 m; body fat = 11.0 ± 1.9%) volunteered to participate in this study. Futsal players performed a futsal-specific intermittent shuttle-run protocol (FIRP) designed to replicate the activity profile of a futsal match. It comprises two blocks of 20-minute activities performed around a shuttle-run along a 15-m distance. The activities performed in the protocol were divided into the following categories: standing (0 km/h), walking (6 km/h), jogging (8.5 km/h), medium-intensity running (13 km/h), high-intensity running (17 km/h), and sprinting (>18 km/h). At pre-protocol, half-time, and post-protocol, the isokinetic torque of the knee flexors (concentric and eccentric actions) and extensors muscles (concentric action) were measured using an isokinetic dynamometer (Biodex System 3, Biodex Medical, Shirley, NY, USA), only in the participant's dominant leg ('kicking leg'). From the peak torque values, the traditional concentric flexor-to-concentric extensor and functional eccentric flexor-to-concentric extensor torque ratios were identified. Analysis of variance (ANOVA) with repeated measures using Bonferroni post hoc tests was used to compare the variables over the time points.
Results: Significant differences in the torque ratios were observed among the tested conditions (Table I). Lower values of conventional torque ratio were observed at the end of the FIRP when compared to pre-protocol; the values at half-time did not differ from the values measured pre-protocol and post-protocol. Regarding the functional torque ratio, lower values were observed at the end of the FIRP when compared to pre-protocol (as occurred with the conventional torque ratio); the values at half-time did not differ from the values measured pre-protocol or post-protocol.
Conclusion: It was concluded that the protocol designed to replicate the demands of a futsal match induced fatigue in the players, reducing the conventional and functional torque ratios at the end of the protocol, indicating a muscular imbalance at the end of exercise. This means that fatigue affected more pronounced the torque production of knee flexors than the knee extensors. Thus, fundamentally exercises focusing on the eccentric strength of hamstring muscles should be privileged aiming to at least reduce the deleterious effects of fatigue, and thereby reduce the chance for the predisposition of hamstring-strain injury in futsal players.

Table:

	Pre-protocol	Half-time	Post-protocol	p
Conventional torque ratio	0.631 ± 0.081	0.603 ± 0.089	0.578 ± 0.088[a]	<0.01
Functional torque ratio	0.955 ± 0.143	0.991 ± 0.121	0.919 ± 0.162[a]	0.01
[a] Significantly different from the pre-protocol value

PO-0357

A NEW KINEMATIC METHOD TO CLASSIFY ALL FOOT STRIKE PATTERNS DURING RUNNING

Max Paquette [1,*]

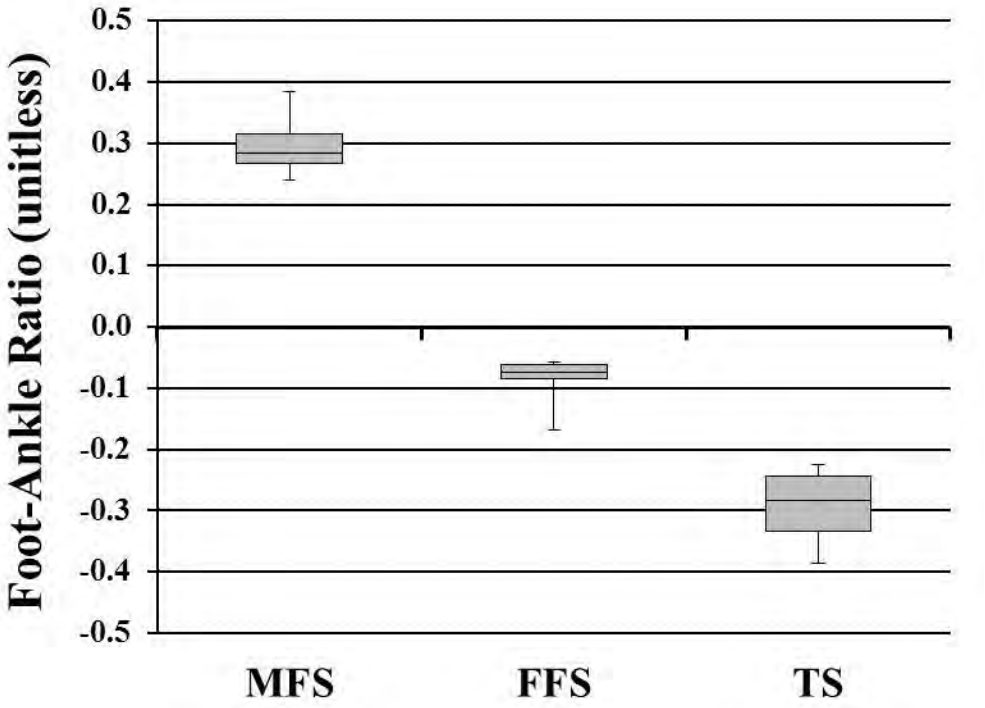
[1]Health & Sport Sciences, University of Memphis, Memphis, United States

Introduction and Objectives: Rearfoot strike patterns are most often studied in biomechanics due to the higher prevalence of rearfoot runners compared to non-rearfoot runners (e.g., midfoot, forefoot and toe strike). Toe striking is less common but observed in some competitive and elite runners but is often lumped into a classification with forefoot runners. There is currently a kinematic (i.e., foot contact angle [1]) and a kinetic (i.e., strike index [2]) method to classify strike patterns and these methods can effectively differentiate rearfoot and non-rearfoot strike patterns. However, non-RFS patterns can often be more difficult to classify with these methods. Correct classification of strike patterns in non-rearfoot runners is important to understand biomechanical differences between all running styles as scientists continue to study running injury risk factors. The objective of this study was to compare a new kinematic method to classify strike patterns with currently accepted methods.

Methods: Six young adults (4 men) completed five over-ground running trials at 3.5m/s±5% using a rearfoot, midfoot, forefoot and toe strike. Subjects warmed up on a treadmill before testing and completed practice trials before each condition. Strike patterns were randomized and verbal instructions were given for each pattern. Strike patterns were visually monitored by the same researcher. 3D motion capture data of the right shank and foot (Qualisys AB) and, 3D ground reaction force data were collected to identify time of foot contact (AMTI, Inc). A new kinematic method to differentiate strike patterns was computed as the ratio of the sagittal plane foot contact angle and ankle range of motion to midstance (Foot-Ankle Ratio; FAR). Foot contact angle (FCA) was measured as the absolute sagittal plane angle formed between a line joining the 5th metatarsal head and the inferior heel and the laboratory floor. Ankle range of motion was measured as the sagittal plane angular excursion of the ankle from foot contact to peak dorsiflexion. Strike index (SI) was computed as the ratio of anterior center of pressure location at foot contact relative to the length of the foot. The means of the five running trials for FAR, SI and FCA were computed and used for analysis. Cohen's d effect sizes (ES) were computed to compare mean differences for each strike pattern classification methods among strike patterns.

Results: All strike patterns showed different FAR (ES = 2.82 – 10.08), FCA (ES = 1.27 – 14.72) and SI (ES = 4.08 – 12.60; Table 1). The ranges of subject means for all methods did not overlap when comparing RFS with MFS and FFS and, MFS with FFS (Table 1). However, when comparing the ranges of subject means between FFS and TS, only the ranges of FAR and FCA did not overlap between these strike patterns (Fig 1).

Figure:



Caption: Fig 1. Boxplot for midfoot (MFS), forefoot (FFS) and toe strike (TS) for the foot-ankle ratio (FAR): the ratio of the sagittal plane foot contact angle and the sagittal plan ankle range of motion (Maximum, 3rd Quartile, Median, 1st Quartile, Minimum).

Conclusion: The findings indicate that FAR, SI and FCA can successfully classify rearfoot, midfoot and forefoot strike patterns, but SI failed to clearly differentiate forefoot and toe strike patterns. The FCA and a new kinematic method to classify strike patterns, FAR, can effectively differentiate all strike patterns including forefoot and toe striking. This preliminary analysis with a small sample size indicates that the two kinematic methods are more effective than a kinetic method (SI) to classify all strike patterns in running. Based on these findings, the FCA would be the most effective method as data collection and computation are simple. A larger sample size will be used to further confirm the effectiveness of these methods in classifying all strike patterns during running.

Table:

	RFS	MFS	FFS	TS
FAR (unitless)	3.14 (1.58,5.14)	0.30 (0.24,0.38) [a]	-0.09 (-0.06,-0.17) [a,b]	-0.30 (-0.23,-0.39) [a,b,c]
SI (%)	12.21 (4.54,22.04)	67.86 (45.15,81.29) [a]	109.24 (98.43,122.75) [a,b]	102.46 (107.04,128.47) [a,b,c]
FCA (deg)	23.68 (17.51,29.93)	6.41 (5.68,7.31) [a,b]	-2.72 (-2.02,-6.79) [a,b]	-9.65 (-7.90,-11.62) [a,b,c]

Notes: [a]: large ES compared to RFS; [b]: large ES compared to MFS; [c]: large ES compared to FFS (ES > 0.8).

Caption: Table 1. A comparison of the foot-ankle ratio (FAR), strike index (SI) and foot contact angle (FCA) strike pattern classification methods for all four strike patterns: rearfoot (RFS), midfoot (MFS), forefoot (FFS) and toe strike (TS). [mean (minimum, maximum)]

PO-0358

THE BIOMECHANICS OF THE LATERAL JUMP SMASH AND FOOTWORK TRAINING IN BADMINTON

Min-Hao Hung [1,*] Jia-Hao Chang [1] Po-Han Chang [1] Yao-Ting Chang [1]

[1]Physical Education, National Taiwan Normal University, Taipei, Taiwan, Republic of China

Introduction and Objectives: To have an advantage in the competition, the lateral jump smash has been used in the badminton. The footwork training improves the skill in lateral jump smash, but only footwork training (without ball) is not accordance with real competition[1]. **Purpose:** to improve the reality in training, this study was measuring the differences between lateral Jump smash training (with ball) and lateral Jump smash footwork training (without ball) in biomechanics. **Methods:** Eight players with 13 ± 2.9 years badminton training experience, all participants were right hand dominant (n=8,23.6 ± 3.3 years, 176.5 ± 3.1 cm, 70.5 ± 8.2 kg). Eight Vicon infrared high-speed cameras (300 Hz) and a Kistler force plate (1500 Hz) were used to collect kinematic and kinetic data respectively. Players were asked to jump three times in lateral Jump Smash Footwork (without ball) and three times laterals Jump Smash (with ball). After smash, they were landing on the force plate and returned to the original position. The Visual3D software was used to process and analyze biomechanics. The Dependent sample t test was performed to compare the joint angle, ground reaction force between two conditions by using SPSS 22.0 (α = .05).

Results: No difference was found between the two conditions at ground reaction force. The main finding was focused on the landing moment. Spike had greater hip abduction (38.4 ± 5.7°) and greater knee flexion (15.5 ± 3°), footwork training had a greater hip flexion (11.6 ± 5.4°). In landing phase footwork had a greater knee flexion and extension range of motion (60 ± 6.1°).

Conclusion: The differences between two training were the joint angles and landing strategy in landing. Hard landing strategy was found in a spike with a ball, and soft landing strategy was found in footwork training.

Table:

Table Mean ± SD (degree) of joint angle			
	footwork	Spike	p value
Hip (initial contact) Abduction (+)/Adduction (-)	33.98 ± 7.79	38.42 ± 5.65	.007 *

PO-0359

USING A DYNAMIC SYSTEM APPROACH AS A MEASURE TO DISCRIMINATE RUNNING WITH DIFFERENT FOOT STRIKE PATTERNS

I.Lin Wang [1] Li.I Wang [2,*]

[1]National Dong Hwa University, Department of Life Science and the Institute of Biotechnology, [2]National Dong Hwa University, Department of Physical Education and Kinesiology, Hualien, Taiwan, Republic of China

Introduction and Objectives: Running is a popular recreational sport. While running, the foot repeatedly contacts the ground. This movement can cause repeated impact forces that result in lower extremity injuries [5;6]. Running exhibits a high proportion of lower extremity injury rates, especially in the knee joint. Three types of foot contact with the ground are observed: rear-foot strike (RFS), mid-foot strike (MFS), and fore-foot strike (FFS) [3]. Different landing patterns cause different impact characteristics. Past studies suggest that FFS method produces a smaller impact force [1;3]. Thus, the purpose of this study was to determine the effect of the strike pattern coordination on lower extremity landing while running to provide information regarding the risk of injury.

Methods: Sixteen habitual RFS runners (height: 1.71 ± 0.10 m; weight: 62.44 ± 9.70 kg; age: 21.44 ± 1.67 years) and four habitual FFS runners (height: 1.67 ± 0.10 m; weight: 57.50 ± 11.70 kg; age: 21.00 ± 0.82 years) served as the subjects. All subjects were university students from the physical education department who volunteered to participate in the study. Kinematic data were collected using an eight-camera motion analysis system (Qualisys motion system, Gothenburg, Sweden) (200 Hz). Ground reaction forces were collected using two AMTI force plates (1000 Hz). Joint angles and angular velocities were interpolated to 100% of the breaking phase. The dynamic system approach was used to analyze the pattern of the inter-joint coordination with the mean absolute value of the ensemble relative phase angle curve value (MARP) [2]. Statistical analysis was performed with SPSS 14.0 for Windows. The significance level was set at $\alpha=0.05$. Independent *t*-test was used to detect differences among groups with different foot strike pattern.

Results: The results are revealed in Table 1. The MARP of knee flexion/extension – ankle inversion/eversion in habitually RFS runners was significant smaller than habitually FFS runners ($P<0.05$). There were no significantly different in MARP of knee flexion/extension – ankle plantar flexion /dorsiflexion and hip flexion/extension - knee flexion/extension between two groups ($P>0.05$).

Conclusion: In the dynamic systems approach, analysis of the MARP values yields an understanding regarding the motion of the two joints, i.e., whether the joints are moving in phase with low individual independence or out of phase with high individual independence [2;4;6]. The present study revealed that the RFS group exhibited relatively in-phase patterns for knee flexion/extension-ankle inversion/eversion inter-joint coordination compared with the FFS group. This in-phase (low-independence) coordination pattern may be associated with increased collision forces [6]. This at-risk motion pattern predisposes runners to injuries. Additionally, Stergiou, et al. [7] revealed that a relatively out-of-phase motion pattern during the stance phase is potentially associated with the desire to reduce the landing load. Inappropriate lower extremity coordination is likely to limit the impact-absorbing capacity of the lower extremities during the stance phase, thus predisposing runners to running injuries [6;7].

Habitual RFS runners potentially decrease the independence of knee flexion/extension-ankle inversion/eversion during the breaking phase of running. This inappropriate lower extremity inter-segment coordination may increase the risk of lower extremity injury.

Table:

Group	RFS	FFS
MARP of knee flexion/extension – ankle inversion/eversion *	0.662±0.21	1.006±0.11
MARP of knee flexion/extension –ankle plantarflexion /dorsiflexion	1.108±0.21	1.058±0.30
MARP of hip flexion/extension – knee flexion/extension	0.848±0.08	0.808±0.09

EFFECTS OF EXTERNALLY DAMPING ON IMPACT-INDUCED SOFT TISSUE VIBRATIONS AND MUSCLE RESPONSES IN LANDINGS

Weijie Fu [1,*] Yu Liu [1] Rui Xia [1] Lingyan Huang [1]

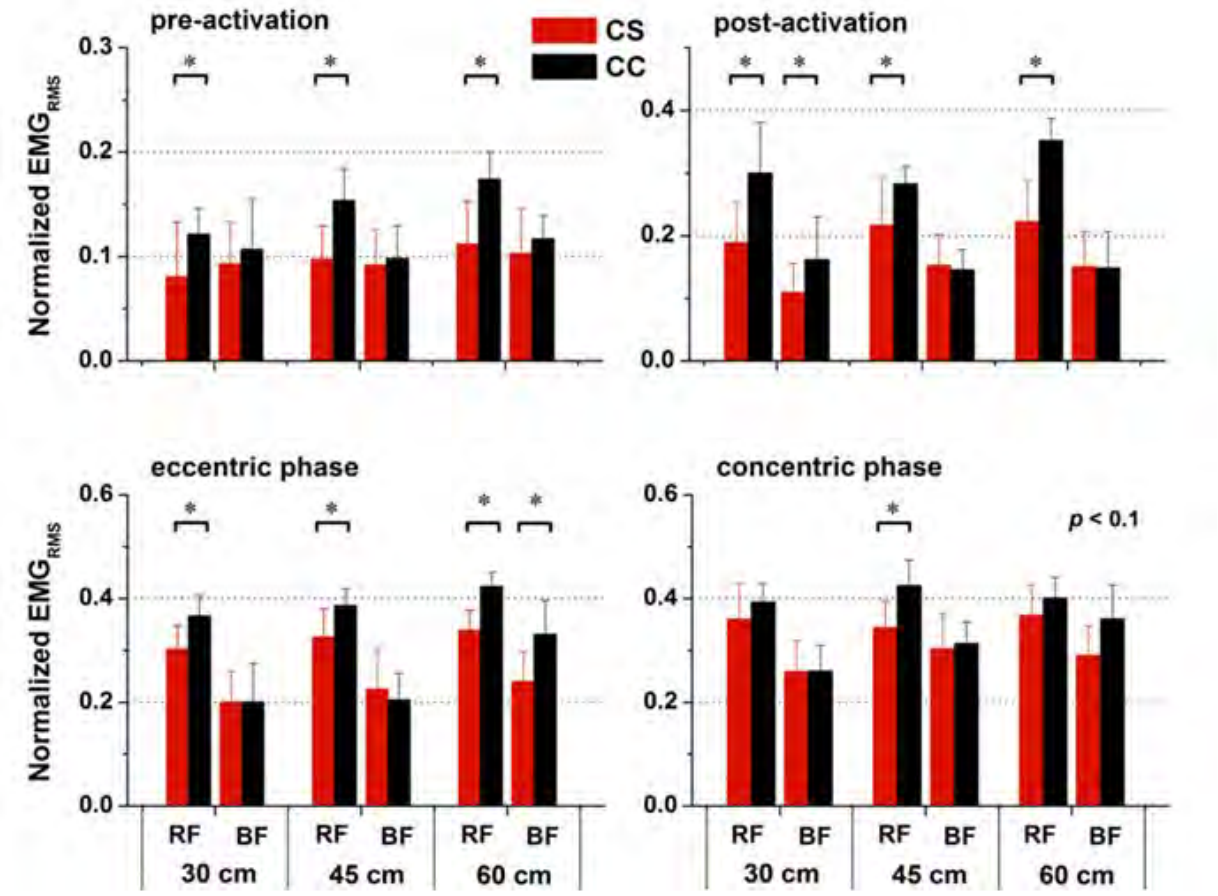
[1] Key Laboratory of Exercise and Health Sciences of Ministry of Education, Shanghai University of Sport, Shanghai, China

Introduction and Objectives: Numerous studies have shown that most physical activities including running and jump/landing experience impacts during ground contact. These impact forces cause large transient shocks that act upon the lower body and excite local vibrations that are either absorbed or transmitted through the soft tissues [1]. A reduction in soft tissue oscillation is considered to be one of the benefits of wearing compression garments in enhancing performance. Theoretically, damping the soft tissue vibrations would decrease the muscle activity and, thus, decrease the needed energy [2]. Therefore, the purpose of this study was to investigate the effect of compression shorts on soft tissue vibrations, and muscle activity in the lower extremity during a drop jump landing task.

Methods: Twelve trained male volunteers (age: 23.7±2.7 years, height: 178.3±2.5 cm, mass: 70.1±4.6 kg) were recruited for this experiment. All were requested to wear two types of shorts [nylon-elastane compression shorts (CS) vs. loose fitting shorts (as a control condition, CC)] to execute three trials of maximal effort drop jump (DJ) from each of height (30, 45, and 60 cm) from a platform. Vibrations of the quadriceps and hamstrings in the dominant leg through the accelerometers were collected using two Biovision biaxial accelerometers (1200 Hz). A Biovision EMG system (1200 Hz) was used to record the EMG signals from the rectus femoris (RF) and biceps femoris (BF) synchronously. The main variables used in this study characterizing the vibration signal included peak soft tissue acceleration (a_{peak}) and the damping coefficient (c) following landing impact for each condition. They were determined using a least-squares minimization method (Levenberg–Marquardt). Meanwhile, root mean square of the muscle activity (EMG_{RMS}) was calculated during the pre-activation, post-activation, eccentric, and concentric phases of the drop jump. A repeated measures ANOVA was used to determine the effects of compression shorts and drop heights on soft-tissue vibrations and EMG activity.

Results: For the soft tissue vibrations, the CS condition showed a significant decrease in the vibration amplitude of quadriceps and hamstring, and an increase in damping coefficient of the corresponding muscles (Table 1). For the muscle activations, the EMG_{RMS} of the RF and BF muscles both showed a significant decrease in wearing compression shorts compared to control condition (Figure 1). Specifically, the EMG_{RMS} of RF when wearing CS was significantly lower compared to CC during pre- & post-activation and eccentric (downward) phases from all heights of DJ; similarly, the EMG amplitude wearing CS compared to CC also showed a decrease in BF during the post-activation of DJ45 and eccentric (downward) phase of DJ60, respectively.

Figure:



Caption: Figure 1 Influence of externally damping (CS: compression shorts; CC: control condition) on the EMG amplitude of rectus femoris (RF) and biceps femoris (BF).

Conclusion: Our results suggest that soft tissue vibration can be reduced by wearing compressive shorts without generating additional muscle activation during drop jump landing. Contrarily, externally induced soft tissue vibration damping might be associated with a decrease in muscular activity of the rectus femoris and the biceps femoris muscles. However, future studies should focus on the possible relationship between soft tissue vibration damping, muscle activity and energy consumption.

Table:

Variables	Muscle groups	Shorts conditions	Landing heights			
			30cm	45cm	60cm	
a_{peak} (g)	Quad	CS	6.85±3.1	10.25±4.9*	11.18±4.1*	
		CC	7.82±3.2	13.16±4.4	14.31±4.2	
	Hams	CS	3.18±1.2*	4.07±1.5	5.01±1.1†	
		CC	4.42±1.9	4.85±1.0	5.92±2.4	
c (s^{-1})	Quad	CS	15.57±1.2	17.21±2.7	19.22±3.5*	
		CC	13.86±3.5	15.67±5.4	16.80±3.1	
	Hams	CS	11.68±5.7	12.93±6.7	13.88±5.7*	
		CC	13.17±5.3	14.69±5.6	16.82±5.7	

***** Significantly different between shorts in the same landing height with $p < 0.05$.

† Significantly different between shorts in the same landing height with $p < 0.1$.

PO-0361

THE PLANE OF ROTATION AT DIFFERENT BASEBALL BATTING HEIGHT

Tang-Yun Lo [1,*] Po-Yao Chuang [1] Yao-Ting Chang [1] Jia-Hao Chang [1]

[1]Department of Physical Education, National Taiwan Normal University, Taipei City, -

Introduction and Objectives: Many researches investigated the difference of body motion in varying hitting conditions and focused on joint angle and angular velocity. But few researches investigated the changes of trajectory which directly affect batting. The aim of this study was to observe motional variation between different batting tasks (high, middle, low) by analysing the plane of rotation.

Methods: Sixteen collegiate baseball players (aged: 22.70 ± 2.05 yr, height: 174.7 ± 2.0 cm, mass: 70.6 ± 6.1 kg) participated in this study. A Vicon 3D motion capture system (250Hz) was used to collect the motion data. Markers were placed on participants in accordance with the plug-in gait marker set, and markers also placed on batting tee, bat head and bat tail. Batting tees are adjustable to simulate the batting situation in different heights (high, middle and low). After warming up, every player was asked to bat 3 times successfully and the trail which has the fast velocity of bat head while ball-bat contact was chosen during each height of task. In order to reduce individual unstable batting motion in interference, the swing phase was defined from the angle between X axis of *global* coordinate system and the line passing through the right shoulder and left shoulder in XY plane was zero to ball-bat contact Kwon3D XP was used to calculate the kinematic parameters. We calculated normal vectors to the plane of rotation by bat (N_B) and upper trunk (N_T) trajectory. The one-way ANOVA with repeated measures ($\alpha = .05$) was used to test the angle between normal vectors so as to observe the relationship between segments (upper trunk and bat) motion in different batting tasks.

Results: The angle between N_B and global Z axis(θ_{BZ}) in high hitting condition was less than in middle condition and in middle condition was less than in low condition. The angle between N_T and global Z axis(θ_{TZ}) in high hitting condition is less than in middle condition andθ_{TZ} in middle was less than in low condition. The angle between N_B and N_T(θ_{BT}) in high batting task was less than in middle and low batting task.

Conclusion: In order to batting successfully, player's motion will be changed with batting height. Many studies indicate that the motion of upper lime is the key factor to batting, nevertheless, upper trunk may also play an improtant role. In this reserch, we observe that the rotation plane of upper trunk and bat are change similarly with batting height.

Table:

Table 1. Angle between vectors in different batting tasks.

	Batting Task	Mean±SD (degree)
θ_{BZ}	High	18.5 ± 5.8^{ab}
	Middle	37.4 ± 7.1^{ac}
	Low	50.5 ± 5.2^{bc}
θ_{TZ}	High	17.7 ± 5.8^{ab}
	Middle	24.1 ± 6.1^{ac}
	Low	33.0 ± 7.8^{bc}
θ_{BT}	High	12.7 ± 5.6^{ab}
	Middle	16.8 ± 6.7^{a}
	Low	19.9 ± 5.5^{b}

significant difference ($p < .05$) : a: high vs.middle, b:high vs. low, c: middle vs. low

SINGLE-CAMERA DEPTH-SCANNING TO MEASURE REAL-TIME PELVIC POSITION AND ORIENTATION DURING TREADMILL GAIT: IMPLICATIONS FOR RISK FACTOR MODELLING

Tom Macpherson [1,*] Jonathan Taylor [1] Tom McBain [1] Matthew Weston [1] Iain Spears [1]

[1] Sport and Exercise, Teesside University, Middlesbrough, United Kingdom

Introduction and Objectives: The pelvic region forms the proximal end of the lower kinetic chain and is routinely assessed due to its reputed relationship with pelvic, spinal and lower limb pathologies (Liebenson, 2004; Sahrmann, 2002; Herrington, 2011). The surrounding musculature provides the control and stabilization necessary for efficient gait (Saunders et al., 2005), and large linear and/or angular oscillations of the pelvis during gait are implicated in musculoskeletal injuries (Saunders et al., 2005). However, these reputed risks and causal pathways are not well understood (Laird et al., 2014).

Several studies have presented protocols to quantify pelvic movements during gait (Schache et al. 2002a; Bickham et al., 2000; Schache et al., 2000). However, they are generally lab-based and time-consuming, which may limit the practicality for use in large-scale trials. Depth sensing cameras, such as the Kinect sensor (Microsoft™, USA), may offer an affordable and pragmatic alternative (Dutta, 2012). The key feature of this technology is the real-time measurement of camera-object distances (depth) on a pixel-by-pixel basis. The raw data from this module is more precise than the better known skeletal tracking module (Dutta, 2012).

Therefore, the aims of this study were to develop techniques and evaluate a single-camera depth scanning approach to the 3D measurement of linear and angular oscillations of the pelvis during treadmill gait.

Methods: Three participants volunteered for the study (age 27.7 ± 1.9 y, height 87.7 ± 2.9 cm and mass 78.0 ± 8.7 kg). Participants undertook a baseline incremental treadmill test to determine their maximal oxygen uptake (O_2max) followed by trials (180s each) at 3 different speeds of locomotion (walking: 5.1-6.0 km/h; jogging: 10.5-11.2 km/h and running: 13.5-14.4 km/h).

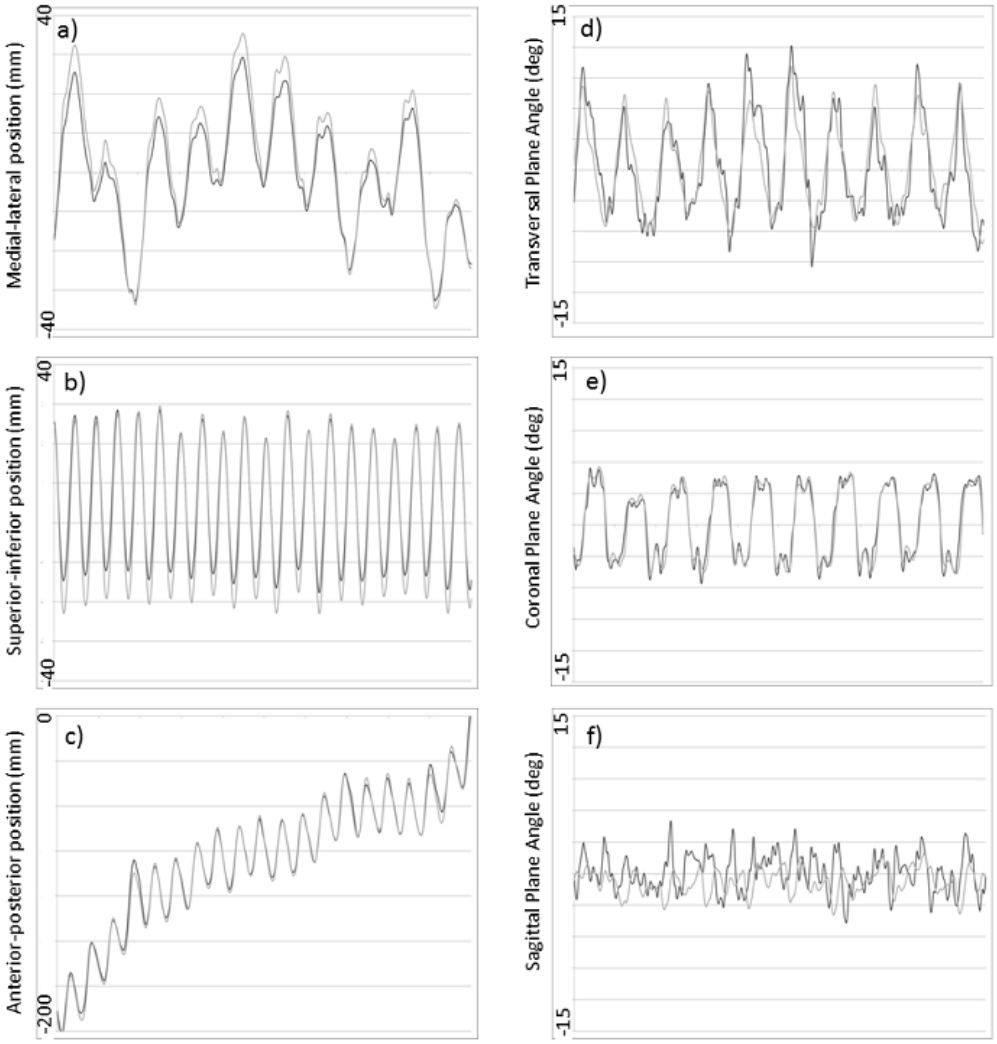
Four retro-reflective disks were positioned bilaterally on the posterior and anterior iliac spines. Pelvic movements were captured concurrently using a single RGBD camera (Kinect™, Version 1, Microsoft, USA) and a 6-camera motion capture system (Vicon MX13 and Vicon Nexus 1.7, Vicon Motion Systems). Depth data for the single camera system was used to reconstruct a surface on the posterior of the lumbo-pelvic complex. The surface was then processed to estimate pelvic orientation position and angular position.

The time-series for the triaxial linear positional (Figure 1a, b and c) and triplanar angular (Figure 1d, e and f) data were used to determine the amplitudes of oscillations for the 6 degrees of freedom on a stride-by-stride basis. These were compared with the data from the 'gold standard'. Individual strides were determined by processing the superior-inferior movements (Figure 1b). The within-trial typical errors (reported with 90% Confidence Limits [90% CL]) of measurement were derived using a custom-written spreadsheet (Hopkins, 2000).

Results: Typical errors for the single-camera system, expressed as a CV (%) were 1.4 (90% CL: 1.0-2.4), 4.3 (3.0-7.8) and 1.4 (1.0-2.6) for the amplitude of oscillation in the anterior-posterior, superior-inferior and medial-lateral directions.

Typical errors of the angular measurements were 9.8 (6.8-18.2), 13.9 (9.6-26.4) and 41.1 (27.5-85.6) in the frontal, transversal and sagittal planes, respectively.

Figure:



Caption: Figure 1. Time-series of data points taken over a 10second interval for self-selected walking in one of the participants. The single-camera system (black line) and the six-camera system (grey line). Positional data in the medial-lateral (a), superior-inferior (b) and anterior-posterior directions (c). Angular rotations are in the transversal (d), coronal (e) and sagittal (f) planes.

Conclusion: The single-camera system offers a safe, rapid, easy-to-use and portable kinematic system as the data it produces compares well with the criterion data for five of the six degrees of freedom tested. This study has shown the single-camera system offers a pragmatic method for kinematic data capture that is suitable for large-scale data collection on the pelvis and risk-factor modelling. However, the system needs to be tested in a much wider populations, which may include clinical or obese populations, for whom small abnormal movements and skin movements may be much more problematic (Schache et al., 2002b).

A BIOMECHANICAL EVALUATION OF THREE NEEDLELESS GRASPING SUTURE TECHNIQUES FOR GRAFT FIXATION

Wei-Ren Su [1,*] Chih-Kai Hong [1] Chih-Hsun Chang [1] I-Ming Jou [1]

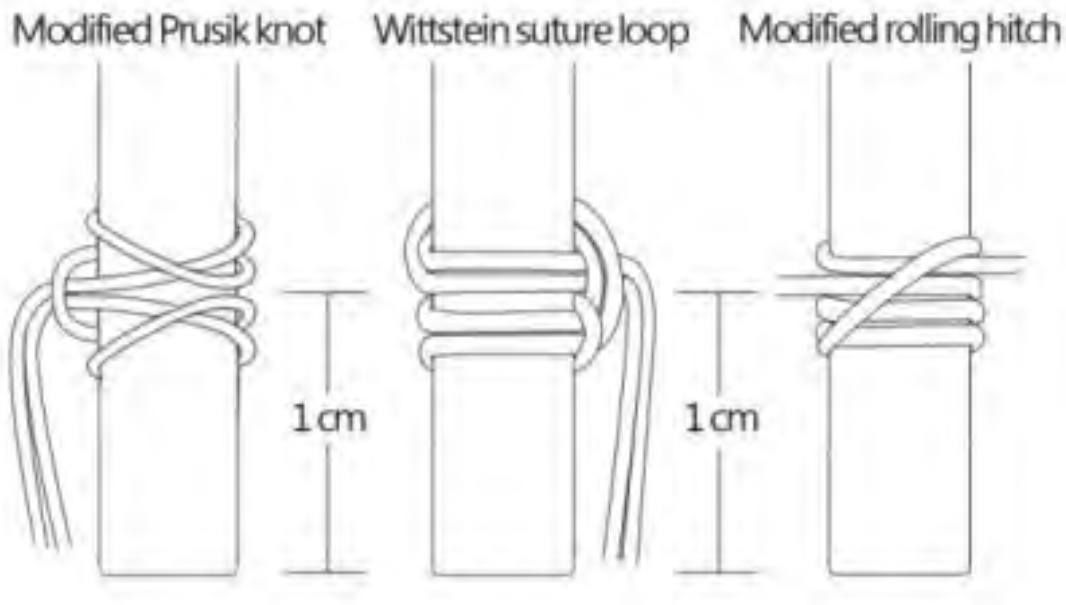
[1]Orthopaedic Surgery, National Cheng Kung University Hospital, Tainan, Taiwan, Republic of China

Introduction and Objectives: The purpose of this study was to evaluate the tendon graft holding strength of needleless grasping suture techniques, namely the modified Prusik knot, Wittstein suture loop and modified rolling hitch.

Methods: 30 fresh-frozen porcine flexor profundus tendons were used and randomly divided into 3 groups of 10 specimens. The experimental procedure was designed to assess elongation of the suture-tendon construct across three different needleless tendon-grasping techniques (Figure). All suture configurations were completed with a No. 2 FiberWire suture (Arthrex). Each tendon was pre-tensioned to 100 N for three cycles, cyclically loaded to 200 N for 200 cycles, and then finally loaded to failure. Elongation, load to failure and mode of failure for each suture-tendon construct were measured.

Results: During the pre-tension phase, the modified rolling hitch had the smallest suture-tendon construct elongation ($P<0.001$) (16.9 ± 5.8%) compared with the modified Prusik knot (31.2 ± 6.9%) and Wittstein suture loop (25.5 ± 8.1%). During cyclic loading, there were no significant differences in elongation for any of the tested suture-tendon constructs (modified rolling hitch (21.2 ± 9.6%), modified Prusik knot (21.4 ± 9.9%), and Wittstein suture loop (26.2 ± 4.5%)). Similarly, the failure load and cross-sectional area were not significantly different across all tested suture groups (Table).

Figure:



Conclusion: The modified rolling hitch technique provided lesser elongation after pretensioning and equal elongation after cyclic loading as well as loading to failure when compared with the modified Prusik knot and Wittstein suture loop techniques tested in this in vitro biomechanical evaluation.

Table:

	Modified Prusik Knot	Wittstein Suture Loop	Modified Rolling Hitch	p-value
Elongation after pre-tensioned, mm (%)	16.1 ± 3.1 (31.2 ± 6.9)[b]	14.2 ± 4.6 (25.5 ± 8.1)[c]	9.8 ± 3.7 (16.9 ± 5.8)[b,c]	<0.001[a]
Elongation after cyclic loading, mm (%)	11.1 ± 4.9 (21.4 ± 9.9)	14.5 ± 2.3 (26.2 ± 4.5)	12.2 ± 5.5 (21.2 ± 9.6)	0.275
Load to failure, N	348 ± 19	356 ± 15	341 ± 14	0.107
Cross sectional area, mm^2	42.4±4.8	43.3±6.1	41.3±3.9	0.235
Failure mode	Suture breakage at the knot	Suture breakage at the knot	Suture breakage at the knot	
[a] Significant difference among the groups with one-way ANOVA test: $P < 0.05$. [b,c] Significant difference between the groups with Bonferroni post hoc test: $P < 0.05$

THE PLANTAR PRESSURE CHARACTERISTICS OF RIGHT-FORWARD LUNGE STEP OF PROFESSIONAL-LEVELLED AND AMATEUR-LEVELLED BADMINTON PLAYERS

Lin Yu [1,*] Qichang Mei [1] Julien Baker [2] Ukadike Ugbolue [2]

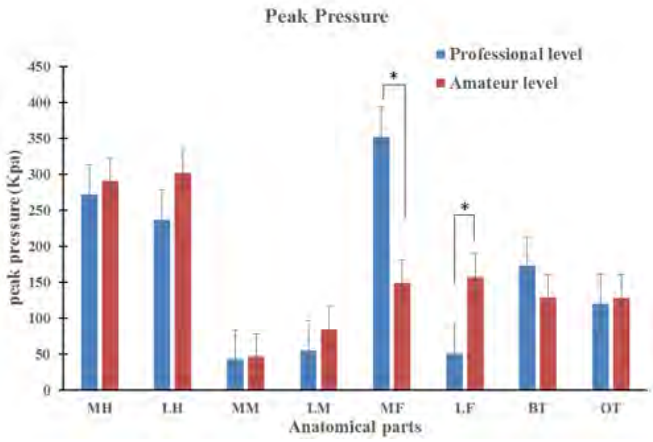
[1]Faculty of Sports Science, Ningbo University, Ningbo, China, [2]School of Science and Sport, University of the West of Scotland, Hamilton, Lanarkshire, Scotland, United Kingdom

Introduction and Objectives: Badminton has gained large amount of participants with its effect of participants' whole body physical capacity exercising (Jérgensen et al., 1987). Lunge as one of the most basic and important footworks in badminton movement has been studied (Fu et al, 2009). The study was aimed to investigate the plantar pressure characters of both professional-levelled and amateur-levelled badminton players. Comparative analysis were made to illustrate the different loading features while performing the right-forward lunge step between badminton players of two levels.

Methods: A total of twelve badminton players, with six professional-levelled and six amateur-levelled badminton players, participated into the test. The Novel pedar-X plantar pressure measuring system was taken to collect the force and pressure on the plantar insole. And the insole was divided into eight anatomical parts, with medial heel (MH), lateral heel (LH), medial midfoot (MM), lateral midfoot (LM), medial forefoot (MF), lateral forefoot (LF), big toe (BT) and other toes (OT). Peak pressure and force time integral were utilized to show the different plantar pressure characteristics of two group badminton players while performing the right forward lunging step.

Results: The peak pressure and force time integral were analysed in the eight anatomical parts. As the result turns out and figure (* indicates the significance level below 0.01) shows, the peak pressure in the medial forefoot (MF) and lateral forefoot (LF) show great significance (with $p<0.01$) between professional-levelled and amateur-levelled badminton players. The peak pressure in the medial forefoot (MF) of professional-levelled players are obviously higher than that of amateur-levelled players. And the peak pressure in the lateral forefoot (LF) of professional-levelled players are significantly smaller than that of amateur-levelled players.

Figure:



Conclusion: The peak pressure difference in the forefoot were linked with badminton players' performance in the court. While finishing the lunging step, the next movement is the preparing action for a defence or strike depending on the competition situations. The higher peak pressure in the medial forefoot part reflected the accurate and fast pushing-back movement of badminton players.

PO-0365

UPPER EXTREMITY KINEMATICS & KINETICS IN YOUTH BASEBALL CATCHERS AND PITCHERS

Gretchen D. Oliver [1,*] Wendi Weimar [1] Hillary Plummer [1]

[1]School of Kinesiology, Auburn University, Auburn, United States

Introduction and Objectives: Biomechanical analysis of youth throwing continues to evolve and has taken on a new resurgence. Up to this point, a majority of research on youth throwing has focused on baseball pitchers. However, another player throws the ball nearly as much as the pitcher but has gone mostly overlooked. The catcher throws the ball back the pitcher after every non-hit pitch, down to second, and even has plays at first. Furthermore, they make all of these throws after rising from a squatting position. Therefore it was the purpose of this study to quantify upper extremity mechanics of youth baseball catchers and pitchers. It was hypothesized that due to the catcher's squat position, and timing demands, that the overhead throwing motion of catchers would be different from the throwing motion of the pitchers.

Methods: A total of 78 youth baseball catchers (N= 25; 10.7 $\pm$ 1.9 yrs; 149.4 $\pm$ 12.3 cm; 44.5 $\pm$ 9.7 kg) and pitchers (N= 53; 11.1 $\pm$ 1.2 yrs; 152.6 $\pm$ 9.8 cm; 46.6 $\pm$ 10.2 kg) volunteered. All participants were tested during the fall baseball season and had not thrown for two days prior to testing. The MotionMonitor™ (Innovative Sports Training, Chicago IL) synched with an electromagnetic tracking system (Flock of Birds Ascension Technologies Inc., Burlington, VT) was used to collect data. Sensors were attached to the following locations: [1] the posterior/medial aspect of the torso at C7, [2] posterior/medial aspect of the pelvis at S1, [3-4] bilateral distal/posterior aspect of the upper arm, [5] the flat, broad portion of the acromion of the scapula, [6-7] bilateral distal/posterior aspect of the forearm, [8-9] bilateral distal/posterior aspect of the lower leg, and [10-11] bilateral distal/posterior aspect of the upper leg. Participants were given an unlimited time to perform their own pre-competition warm-up. Then the catchers were instructed to catch a pitched ball and throw maximum effort to a position player at second base (84.85 feet; 25.86 meters) as they would if trying to throw out a runner stealing. Pitchers were instructed to throw maximal effort fastball for a strike over a regulation distance (46 feet; 14.02 meters) to a catcher. Kinematic & kinetic data were analyzed at the events of foot contact (FC), maximal shoulder external rotation (MER), ball release (BR), and maximum shoulder internal rotation (MIR). The fastest throw for each participant was chosen for analysis.

Results: A one-way ANOVA revealed significant differences ($p \leq 0.05$) between upper extremity kinematics and kinetics in youth baseball catchers and pitchers. At FC, the catchers had significantly greater shoulder distraction forces. At the events of BR and MIR the pitchers displayed significantly greater shoulder elevation (see Table 1).

Conclusion: It was hypothesized that catchers and pitchers would utilize different throwing mechanics, due to the different demands of the specific throws. For example, pitchers have a target and a motion that is below the starting position of the throw, while catchers have a target and motion that is above the starting position. Further, pitchers are able to control the time to release, while catchers have the constraint of the base runner. It is clear that pitchers and catchers do use different kinematics and kinetics to achieve the respective throwing motions. Further analysis is needed to determine whether it the timing demand or the elevation demands that bring about these results.

A BIOMECHANICAL CASE STUDY ON THE TAKEOFF MOTION OF A JAPANESE WOMAN JUNIOR LONG JUMPER - POSSIBILITY OF THE EFFECT MUSCLE STRENGTH TRAINING ON THE JUMPER'S TAKEOFF MOTION -

Ikko Omura [1,*] Hiroyuki Koyama [2] Akira IIboshi [3] Michiyoshi Ae [4]

[1]Kagoshima Women's College, Kagoshima, [2] Kyoto Univ. of education, Kyoto, [3]Kagoshima Univ., Kagoshima, [4]Tsukuba Univ., Ibaraki, Japan

Introduction and Objectives: We studied the takeoff motion of the long jump for the various level athletes from views point of kinematic data and the standard motion obtained by averaging the motion of the elite athletes. As for the Japanese junior women long jumpers, their motion of the upper body (trunk) during the takeoff phase was remarkably different from that of Japanese men junior long jumpers (Omura.2012). Although the Japanese junior women long jumpers leans the trunk backward during the takeoff phase, the Japanese Junior men jumpers leans the trunk forward during the takeoff phase. Such trunk motions observed in the Japanese junior women jumpers might be due to poor muscle strength of the trunk, resulted in a lower horizontal velocity at the touchdown and release of the takeoff phase. Therefore, focusing muscle training on the trunk of the women junior jumpers might be effective to improve the trunk motion and horizontal velocity during takeoff phase. The purpose of this study was to investigate the effect of the trunk muscle strength training on the takeoff motion of a Japanese junior woman long jumper.

Methods: The subject was a Japanese woman junior long jumper with her personal best record of 6.16m and the second place at the final of 2014 Japan High School T & F Championship. To investigate the effect of the trunk muscle strength training on the long jump takeoff motions, two competitions were filmed. The 1st competition held at September in 2013 and the best trial was 5.76m (Trial-5.76m). After that, we suggested to her coach to introduce the muscle training emphasized on the upper body muscles. Then, she executed upper body muscle training such as six types of abdominal and back muscles, Bench press and Chin up six times per week for seven months. The 2nd competition held at May in 2014 and best trail was 6.16m (Trial-6.16m). In both competitions, the digital video camera was placed at perpendicular to the takeoff board, and filmed the takeoff motion of the jumper with 60f/s. Best trial of each competition was analyzed using FRAME DIAS system (DKH Co., Japan).

Results: The total number of Sit up within 30 seconds increased 13 reps. Bench press and Chin up improved to 25kg and 5 reps, respectively. Percent FAT of the body at Trail-6.16m was 2.2% lower than that of Trial-5.76m. These results suggested the effect of muscle strength training.

The horizontal velocity at the touchdown and the release of the takeoff for the Trial-6.16m was greater than that of Trial-5.76m (touchdown velocity were 9.15m/s vs 8.56m/s, release velocity were 7.45m/s vs 7.30m/s). And also, the vertical velocity at the release of the takeoff for the Trial-6.16m was greater than that of Trial-5.76 (2.83m/s vs 2.68m/s). Furthermore, the takeoff angle of the Trial-6.16m tended to be greater than those of the Trial-5.76m (20.8 deg. vs 20.1 deg.). According to these results, Trial-6.16m, personal best record, might be due to the greater values of the horizontal velocity at the touchdown of the takeoff, the vertical velocity at the release of the takeoff, and the takeoff angle.

Interesting changes observed in the trunk segment during the takeoff phase between Trial-5.76m and Trial-6.16m. Trunk segment angle at the touchdown of the takeoff foot for Trial-5.76m showed large negative value (i.e. the trunk leans backward) compared to Trial-6.16m. If the jumper keeps lean the trunk backward at the takeoff, the horizontal velocity will decrease remarkably due to huge mass of trunk. Therefore, smaller horizontal velocity at the touchdown of takeoff for Trial-5.76m might be caused by the large negative trunk angle. The trunk segment angle during the takeoff phase for Trial-6.16m showed positive value (i.e. the trunk leans forward) at the middle of the takeoff phase, resulting in greater release velocity. The maximum knee joint angle of the supporting leg for the Trial-6.16m during the takeoff phase showed small value (i.e. more knee joint flexion) compare to the Trial-5.76m. In this study, the subject did not execute special long jump practice emphasized on upper body during the takeoff phase except for upper body muscle strength training during seven months training session. Seven months muscle training improved the muscle strength of the upper body, and the subject gave us following comment: "I feel that my upper body becomes stronger than before by the strength training. So, I could maintain the approach velocity during the takeoff and do the takeoff motion more powerfully".

Conclusion: Based on this study, to strengthen the upper body for the junior woman jumper with weak muscle strength might be more effective way to improve the takeoff motion and enhance the athletic performance.

RUGBY SCRUMMING SUCCESS IS RELATED TO THE SCRUMMING KINETICS BUT NOT TO THE ANTHROPOMETRY OF THE PLAYERS IN A SCRUM

Sam Kerr [1,*] Andrew Green [1] Chloe Dafkin [1] Warrick McKinon [1]

[1]School of Physiology, University of the Witwatersrand, Johannesburg, South Africa

Introduction and Objectives: The rugby scrum is an integral part of the game of rugby used to restart the game after a minor transgression. The scrum contest consists of the forward packs from opposing teams involved in a physical push for the ball. The effectiveness of different scrumming techniques and the physical and anthropometric characteristics of individual rugby players have previously been studied to optimize successful scrummaging. However, the specific factors that contribute to scrumming success are currently uncertain. Therefore, the aim of this study was to determine predictors of a winning scrum by testing whether anthropometric variables, pushing force and direction, subjective ratings of fatigue and effort, prior injury and experience are related to scrumming success.

Methods: Sixteen amateur male rugby players (age: 19-48 years) competed in ten successive scrums; each with a different permutation of player positions. The cumulative properties for different scrums with the following recorded variables were compared between winning and losing scrums: scrum force and direction (recorded for each player individually using a customised scrumming machine equipped with four load cells so that the kinetics of pushing [pushing force magnitude and centre of pressure] could be calculated); anthropometric measures (height, mass, body mass index (BMI), muscle mass and fat mass); injuries and playing experience (obtained from questionnaire data) and subjective ratings of exertion and fatigue (measured using the Borg scale and Visual Analogue Scale respectively).

Results: Winning scrums consisted of players that produced a significantly greater force (2061.05±110.13kg vs. 1890.88±110.13kg, $P<0.05$) than the losing scrums. Winning scrums were also directed in a more upward and lateral direction, than losing scrums. There were also significantly more concussions in the winning scrum compared to the losing scrum (3.40±0.84 vs 1.60±0.84, $P<0.05$). In contrast, body mass, body fat and body muscle percentage, BMI, playing experience, subjective ratings of effort and fatigue as well as current injuries did not significantly contribute to winning scrums ($P>0.05$).

Conclusion: Scrum success, was directly related to a forward packs' larger cumulative scrumming force (both as a total force and relative to the scrum mass) as well as scrumming force directed to the right, in an upwards direction, and a greater number of total concussions. In contrast, body mass and playing experience, which previous studies have attributed to scrum success, were not proven in this study. The current study has important relevance for rugby players, as it highlights factors players may want to focus on, giving one player an advantage over another in team selection and scrum success. For greater scrumming success coaches should focus on force production optimization in players involved in the scrum.

PO-0368

FUNCTION OF THE ADDUCTOR MUSCLES DURING MAXIMAL VELOCITY SPRINTING

Yuji Ohshima [1,*] Norihisa Fujii [2]

[1]Doctoral Program in Physical Education, Health and Sports Sciences, [2]Faculty of Health and Sport Sciences, University of Tsukuba, Ibaraki, Japan

Introduction and Objectives: The hip joint torque around flexion-extension axis has an important role on sprint running ability (Dorn et al, 2012). In addition, Sugisaki et al. (2012) indicated the larger adductor muscles were advantageous for achieving higher sprint performance because those muscles act as a hip flexor at extended position. On the other hand, Ohshima et al. (2014) indicated that during the terminal support phase, the hip adductor torque drove forward the hip joint of support leg. But, it is not clear that how much the adductor muscles produce the hip flexion torque and the hip adduction torque.

Therefore, our objectives were (1) to quantify that how much the adductor muscles produce the hip flexion torque and the hip adduction torque during the terminal support phase by estimating muscle force, and (2) to clarify the function of the adductor muscle during the terminal support phase.

Methods: Eight male sprinters volunteered for the present study. The participants ran 60m with the maximal effort from a standing start position. Ground reaction forces (GRFs) of the right support phase was obtained with a force platform (Kistler, Wintherthur, Swiss), operating at 1000Hz, which was placed at the 50m mark from the start. At the same time, 3D coordinates of 47 reflective markers on a body were recorded with a motion analysis system (Vicon, Oxford UK.) using 20 cameras (MX-T20), operating at 250Hz. Coordinates of the markers were smoothed using a fourth-order Butterworth low-pass-digital-filter at cutoff frequencies based on the residual method of Wells and Winter (1980). The cutoff frequencies ranged from 7.5Hz to 15.0Hz.

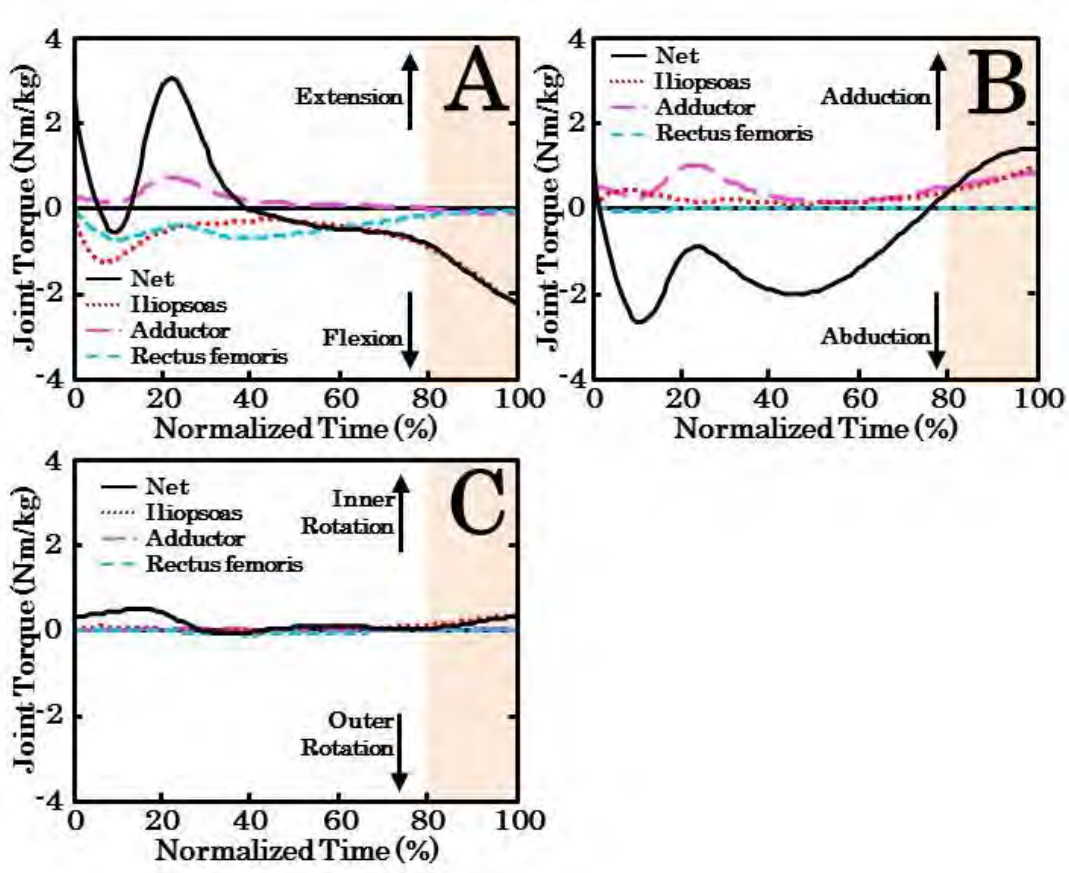
In order to estimate muscle forces about support leg, the musculoskeletal model of support leg comprised 43 Hill-type muscles was developed by using OpenSim (Delp et al., 2007). The problem regarding distribution of the total torque between muscles was resolved by using optimization. The objective function (J) was to minimize activation cubed, summed across all joints. The constraint condition was to match the net joint torques of all muscles with those estimated by an inverse dynamics approach. The time series data of support phase were normalized to the time of a step as 100%.

Results: Running velocity at the 50m mark was 9.24 ± 0.33 m/s. As shown in Figure 1, sprinters exerted the hip flexion torque and adduction torque during the terminal support phase (80-100%). The hip flexion torque was generated mostly by iliopsoas, but hardly by adductor muscles. And the hip adduction torque was generated by iliopsoas and adductor muscles. From these results, it is obvious that the adductor muscles do not act as the hip flexor. The causes we speculated were as follows. First, the adductor muscles' moment arm about the hip flexion torque is very short during the terminal support phase. Second, if the adductor muscles exerted the larger muscle force to enhance the contribution of hip flexion torque, the constraint condition to estimate muscle forces would not be satisfied because the hip adduction torque by the adductor muscles would be large. Furthermore, the objective function would not be minimum value because

the abductor muscle group would exert the larger muscle force to match the hip adduction torque by forces of all muscles with that estimated by an inverse dynamics approach.

Therefore, during the terminal support phase, it is possible that the hip adductor muscles do not act as the hip flexor, but have the function that drives forward the hip joint of support side.

Figure:



Caption: Averaged pattern of hip joint torque during support phase. A: Flexion-Extension, B: Adduction-Abduction, C: Inner-Outer Rotation

Conclusion: The important results of this study are as follows: (1) the hip flexion torque was generated mostly by iliopsoas, and the adductor muscles did not act as the hip flexor. (2) The hip adduction torque was generated by iliopsoas and adductor muscles. (3) The function of adductor muscles was to drive forward the hip joint of support side.

PO-0369

THE BENEFITS OF TAI-CHI EXERCISE ON BALANCE CONTROL DURING STAIR-TO-FLOOR TRANSITION

Chenfu Huang [1,*] Tzu-Hsiang Yang [1]

[1]Physical Education, National Taiwan Normal University, TPE - Taipei, Taiwan, Republic of China

Introduction and Objectives: Downstairs walking was in turns consisted of forward walking and downward descending. The transition strides were constituted two discrete walking patterns, and as such were inherently variable and unstable. Increased falls were occurred during the transition strides before and after stair walking [1]. Injuries related to falls included muscle strains, fractures and even more serious complications.

Center of pressure (CoP) has been defined as the neuromuscular response to shifts in the body's center of mass (CoM), and evaluation the CoP trajectory and CoM-CoP separation during stair negotiation have been used as indicators of dynamic stability on stairs among the elderly [2]. Due to the decline of physiological function, the safety precautions were utilized in older adults, such as lesser A-P and M-L CoP displacement, lower average CoP velocity compared with young adults [2]. Tai-Chi (TC) exercise has been found to improve the abilities of functional movement in daily life in elderly. The purpose of this study was to investigate differences in CoP characteristics during stair-to-floor transition between TC and normal elders.

Methods: The CoP data of 12 Tai-Chi elderly practitioners (Tai-Chi training experience: 10.2±3.3 years; age: 73.0±6.0 years; height: 1.67±0.06 m; weight: 58.5±6.0 kg) and 14 matched control elders (age: 65.6±2.1 years; height: 1.64±0.07 m; weight: 65.6±2.1 kg) were obtained by a Kistler force plate (1000Hz), with negotiating stair descent transiting to level walking at self-selected speed. Participants were aksed to place oly one foot on each step (foot-over-foot). The average CoP velocity was defined as total CoP displacement dividing by stance duration. The peak A-P and M-L CoP displacement were also analysed. Differences in variables between two groups were assessed using t-test (α=.05).

Results: Results revealed as table 1, TC group had wider M-L CoP displacement and faster average CoP velocity. TC group descended at faster speed and had larger stride length. There were no differences in A-P CoP displacement and stance duration.

The backward displacement of the CoP during stair descent generates the forward momentum necessary to initial gait [3]. In previous studies, increased A-P CoP displacements were observed during level walking, stepping over an obstacle and stair descent after TC training. In the study, there were similar in A-P CoP displacement between two groups. However, the benefits of TC exercise reflected on faster descending speed and larger stride length, instead of the possible greater A-P displacement.

In frontal plane, TC group showed greater M-L displacement during stair-to-floor transition. The greater M-L displacement is likely the results of improved coordinated action of the hip abductor and adductor muscles after TC training [3]. It is important for the maintenance of lateral stability in elderly subjects.

The CoP velocity provides valuable important information about how individuals modulate gait when negotiating various stairs [3]. TC groups showed faster CoP velocity, may reflect enhancement in the maintenance of dynamic balance. The

current study was a cross-sectional study, differed from previous longitudinal studies. The benefits of long-term TC exercise (over 7 years) might be slightly different.

Conclusion: TC exercise influenced generation of forward momentum via greater stride length instead of A-P displacement, and improved the maintenance of balance via greater M-L displacement and CoP velocity.

Table:

	TaiChi (n=12)	Normal (n=14)	*P*
A-P displacement (cm)	10.79 ± 2.03	10.44 ± 3.82	
M-L displacement (cm)*	8.16 ± 1.31	4.22 ± 1.68	0.00
CoP velocity (cm/s)*	51.9 ± 18.0	35.1 ± 9.6	0.01
Duration (ms)	663 ± 77	678 ± 103	
Stride length (m)*	0.50 ± 0.06	0.34 ± 0.06	0.00
Descending velocity (m/s)*	0.68 ± 0.08	0.62 ± 0.07	0.02

BIOMECHANICAL AND PHYSIOLOGICAL PREDICTORS OF FALLS IN HORSE RIDERS

Sam Kerr [1,*] Andrew Green [1] Chloe Dafkin [1] Yoshin Barnabas [1] Warrick McKinon [1]

[1] School of Physiology, University of the Witwatersrand, Johannesburg, South Africa

Introduction and Objectives: In horse riding, the rider's seat and posture play an important role in the communication with the horse and balance of the horse and rider. The incorrect seat, whilst being uncomfortable for both the horse and rider, also disrupts effective control over the horse and puts both the horse and rider at risk of injury. Falling from the horse is the most common cause of injury in equestrian sports. Literature suggests that improving elements of posture, balance, flexibility and synchronized movement between the horse and rider enhances rider skills thus should subsequently reduce the risk of falls and injury. Therefore, the aim of this study was to determine whether the incidence and frequency of equestrian sports related falls could be predicted by various biomechanical, anthropometrical and physiological attributes of the riders.

Methods: Thirteen experienced horse riders each rode the same horse at the trot and the canter. Retro-reflective markers were attached to anatomical landmarks of the horse and rider and tracked using a 6 camera kinematic system at 250 frames/second. The kinematically calculated variables included head straightness and back straightness. Horse-rider movement phase delay (an objective measure of horse-rider synchrony) was also determined for each horse and rider for each gait. Incidence of falls and their causes were retrospectively documented for the previous 12 months. Anthropometric and physiological measurements of the riders included: height, weight, balance (the standing stork test), flexibility (sit and reach test), grip strength (hand held dynamometer), lower leg power (vertical jump test) and reaction time. Correlations were run to determine relationships between the variables and number of falls/ incident rate ratios (IRRs) for falls per ride respectively. A stepwise multiple regression model was generated for the most predictive variables of falls.

Results: Age ($r=-0.60$, $p=0.03$), balance ($r=-0.64$, $p=0.02$), flexibility ($r=0.59$, $p=0.04$) and back straightness whilst cantering ($r=0.61$, $p=0.03$) were significantly correlated to the number of falls. Body mass ($r=0.55$, $p=0.04$) and phase delay for trot ($r=-0.80$, $p<0.01$) were significantly related to IRRs for falls per ride. Grip strength, lower leg power and reaction time were not related to the number of falls or IRRs. Back straightness ($r=0.59$) and BMI ($r=0.58$) were positively related to horse shying behaviour ($p<0.05$). Back straightness was also significantly correlated to horse refusal at a jump ($r=0.60$, $p=0.03$). A greater phase delay was found to be the most predictive variable of falls ($\beta=0.541$, $p<0.001$).

Conclusion: Various physiological attributes and biomechanical variables of the rider were able to predict equestrian sports related falls. This study demonstrated the importance of improved balance and flexibility as well as optimizing the synchrony of movement between horse and rider while maintaining the correct upright seat (back straightness) to minimize the risk of falls.

PO-0371

RELIABILITY OF DOLYO CHAGUI KICK IN TAEKWONDO DESCRIBED BY HIP AND KNEE JOINT ANGLES

Afonsa J. Silva [1,*] Ricardo ML Barros [1] Jerusa PR Lara [1]

[1]Faculty of Physical Education, University of Campinas, Campinas, Brazil

Introduction and Objectives: Taekwondo (TKD) is martial art which uses kicks and punches as offensive techniques in combat. Biomechanical analyses of kicks in TKD are usually described in the literature and commonly use kinematic variables such as hip and knee joint angles [2,4].

Therefore it is important to establish the reliability of the measurement procedure to know how strongly measurements of the same group resemble each other [3].

Thus the aim of this study was to evaluate the reliability of joint angles of kicking and supporting legs during the execution of Dolyo Chagui in Taekwondo.

Methods: Seventeen black belt male athletes of TKD with age 26 (7.5) years, height 1.77 (0.08) m, mass 76.3 (10.3) kg and 12 (5.6) years of experience, voluntarily participated in the study.

The DVideo kinematic analysis system was used to obtain the three dimensional coordinates of markers [1]. The system consisted of five Basler cameras (A602fc) working at 100 Hz. Sixteen anatomical markers were tracked, modeling the athlete's body with five segments: pelvis, thighs and shanks (right and left). The hip joint was represented with three degree of freedom and the knee joint with only one (flexion/extension). An extra marker was located at the sparring doll head.

The athlete performed three repetitions with the preferred limb. As a target was used a sparring doll positioned in front of the athlete. The kick movement was analyzed in three conditions: Start, Execution Phase and Contact. An algorithm based on the analysis of the anterior-posterior velocity of the lateral malleolus was designed to objectively determine those conditions. The Start Condition was assumed to be the moment previously to the first detectable malleolus movement towards the target. The Contact was defined at the moment of the first detectable movement of the doll's head marker. The Execution Phase was defined between the Start and the Contact. The minimum and maximum values of each variable during the execution phase were analyzed in terms of reliability.

Sixteen variables were tested. Hip three joint angles and angular velocities; knee flex-extension angles and the corresponding angular velocities, these in supporting and kicking legs. In order to test the absolute agreement of variables between subjects and observations the intraclass correlation coefficient (ICC) was used. A two-way variance model was adopted, which assumed the random row and column variable as sources of variance. In this way the ICC case 2A1 was used, which is interpreted as the degree of absolute agreement among measurements [3]. ICC classification: Poor (ICC≤0.4); Satisfactory (0.4<ICC<0.75); Excellent concordance (ICC≥0.75)

Results: Table 1 presents the results obtained. The majority of knee and hip joint angles presented ICCs with excellent concordance with the exception of the knee angle at contact. The angular velocity rarely presented excellence concordance, ranging from poor to satisfactory.

To the best of our knowledge a study comparing the reliability of such variables in Taekwondo kicks was not yet published in the literature. The results pointed out to an excellent reliability of joint angles. The angular velocities analyses revealed not so good, but satisfactory results. The reasons for that can be due to increased intra-subject variability or also due to the possible error propagation related to the numerical procedures to obtain the derivate. In this study, the subjects were all well-trained black belt athletes that can explain the low variability in the execution detected by the ICC analysis. Future studies are necessary to establish the reliability of kinematic variables among different age or level groups.

Conclusion: The reliability of Dolyo Chagui in Taekwondo in well-trained athletes was excellent with relatively worst reliability to the variables related to angular velocities. The study suggests that kinematical analyses of aekwondo kicks can provide reliable results.

Table: Table 1 Intraclass correlation coefficients - ICC of hip and knee joint variables during the execution of Dolyo Chagui in Taekwondo.

PO-0372

RELATIONSHIP BETWEEN GROUND REACTION FORCE AND LOWER LIMB MUSCLE PRE-ACTIVATION AFTER AN 8-WEEK BAREFOOT TRAINING PROGRAM

Nicholas Tam [1,*] Janie Astephen Wilson [2] Ross Tucker [1]

[1]Human Biology, UCT/MRC Research Unit for Exercise Science and Sports Medicine, University of Cape Town, Cape Town, South Africa, [2]School of Biomedical Engineering, Dalhousie University, Halifax, Canada

Introduction and Objectives: Previous research has suggested that muscle activation strategies and resultant kinematics prior to initial ground contact influence loading rate. This has been shown with neuromuscular modelling of muscle activity and lower limb segment velocity prior to ground contact to determine its influence on the loading of structures . This may be practically relevant as clinicians may be able to focus on modulation of certain muscle groups to affect treatment or prevention of injury.

As initial loading rate occurs early during stance, it may be of value to consider muscle activation immediately prior to ground contact. The modelled effect of muscle activation during the swing phase on the initial loading rate found that increased hip flexor activity throughout swing phase decreases initial loading rate and the impact peak by modulating mid-swing kinematics and reducing landing velocity.

The aim of this study was to describe the neuromuscular activity and examine the initial loading rate, before and after a systematic and progressive 8-week pure barefoot training programme. We hypothesised that posterior muscle groups including ankle plantarflexors would display increased muscle activity during the pre-activation in runners with lower loading rates. Further, we hypothesised that the muscles around the hip that both mobilise and stabilise this joint and the lower limb would be related to the initial loading rate. This would be the result of learned neuromuscular responses prior to landing that modulates the landing posture, joint moments and energy absorption of the lower limb prior to ground contact in response to the barefoot training programme.

Methods: Twenty-one runners completed an 8-week progressive barefoot running training programme. Before and after this intervention, ground reaction force and surface electromyography data were collected in the barefoot and shod condition. Pre-activation and stance phase activity of the gluteus medius (GM), ;biceps femoris (BF);rectus femoris (RF);peroneus longus (PL);tibialis anterior (TA) and gastrocnemius lateralis and medialis (LG and MG) were assessed, along with initial loading rate.

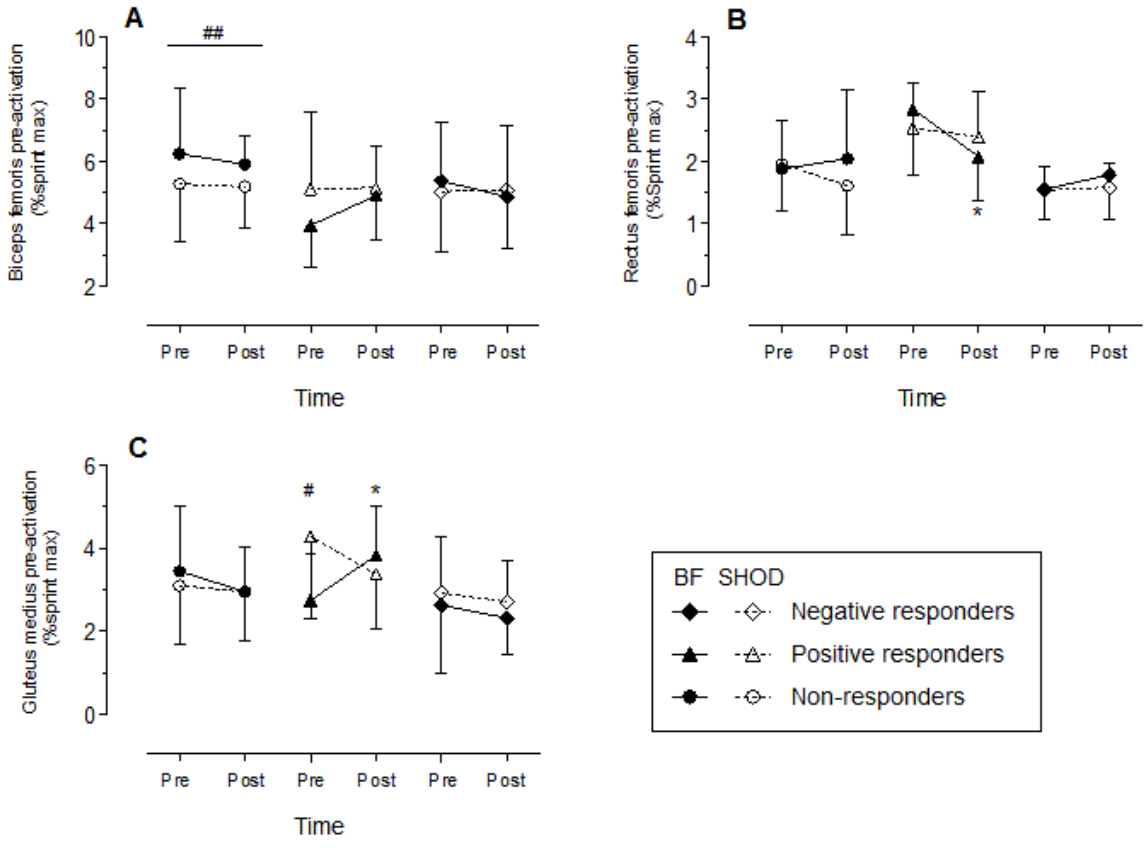
The raw EMG signal was processed using a 15–500 Hz band pass filter. The data were smoothed using route mean squared analysis, (50ms). The processed EMG from the fastest sprint was analysed. The sub-maximal EMG data from clamped speed trials were expressed as a percentage of the fastest sprint (%sprint max). Average EMG activity was calculated for pre-activation and stance phase, reported as a percentage of maximal sprint activity (%sprint max).

To explore the individual response to the progressive barefoot training programme, individuals were segmented in three groups according to a change >1 SD of the initial barefoot loading rate group mean. This produced the groups, namely non-responders (<20 BW·s-1 in loading rate pre- and post-training programme), positive responders (decreased >20 BW·s-1) and negative responders (increase >20 BW·s-1).

A 2-factor ANOVA was used to investigate differences between variables pre- and post-training programme factoring for footwear condition. Further analyses between different group responses for the variables were also assessed. A Tukey's post-hoc analysis was used when appropriate. Relationships between EMG and initial loading rate variables were further assessed with Pearson correlations. Differences were deemed statistically significant at $p<0.05$

Results: LG and MG pre-activation were greater in the barefoot condition before and after the training intervention. This difference was also seen in the LG during stance phase. GM activity during stance phase was increased post-training intervention in both footwear conditions. MG pre-activation was associated with lower initial loading rates before the training programme, while after GM, PL and TA pre-activation when barefoot were associated with initial loading rate after training. Runners who decreased loading rate after training displayed increased BF and GM activity and decreased RF activity when barefoot

Figure:



Caption: Changes in biceps femoris (A), rectus femoris (B) and gluteus medius (c) pre-activation in the responder groups

Conclusion: The inverse relationship between loading rate and posterior muscle group pre-activation and the positive relationship with TA activation suggests that a neuromuscular strategy, which presumably alters the stiffness and kinematics of the lower limb joints, contributes to ground reaction forces. Training-induced changes in GM activity, and the specific changes occurring in the positive responders who reduce loading rate, suggest that neuromuscular strategies can be acquired through training, though the extent and nature of these changes requires further investigation.

PO-0374

KINEMATICS OF BACK MOVEMENT AND LOWER LIMB POWER ARE RELATED TO THE SCRUM FORCE OF INDIVIDUAL RUGBY TIGHT FORWARD PLAYERS

Andrew C. Green [1,*] Chloe Dafkin [1] Benita Olivier [2] Sam Kerr [1] Warrick McKinon [1]

[1]School of Physiology, [2]School of Therapeutic Sciences, University of the Witwatersrand, Johannesburg, South Africa

Introduction and Objectives: Scrummaging is an essential component of rugby and was a designed to be a simple contest to restart the game after a minor transgression had occurred. The scrum contest consists of the forward packs from opposing teams involved in a physical push for the ball. An effective scrum requires the coordinative power of the team with the contribution from individuals influencing the overall outcome of the scrum. However within the modern rugby game the scrum contest has become vital to the team's success, with a winning scrum changing the course of the game and even the outcome. Research regarding the scrum is primarily aimed at injury prevention with less focus on the performance of individual scrum technique. Therefore this study aimed to identify whether individualised measurements of body anthropometry, playing experience, scrumming kinematics (technique), or lower body explosive power would predict scrumming kinetics (scrumming force production). The identification of such predictor variable may assist could assist coaches when choosing teams, or focus an individual's training in the attempt to improve performance.

Methods: The scrumming forces of twenty-eight amateur rugby forward players (experience: 9.8 ± 6.6years; mass: 103.6 ± 14.0 kg) were assessed individually using a custom instrumented scrum machine equipped with four load cells. All scrum force kinetics were measured on an outdoor rugby field. All participants were injury free at the time of measuring and all players were rugby tight forwards (inner scrum players). Lower limb power was measured using a vertical jump height, being the difference of the outstretched arm while standing and the outstretched arm at maximal point during the jump. Vertical jump power was calculated as vertical jump height multiplied by body mass.

Kinematic data was collected on a sub-sample of 21 tight forward players (experience: 8.2 ± 4.2 years; mass: 103.0 ± 12.1 kg), using an 18 camera system recording at 100Hz. Subsequent analysis was done in MatLab using custom written scripts. Flexion of the back occurring at the hips and bilateral flexion of the knees and ankles were measured. The change in angle from starting point to the point of maximal force was used.

Results: The maximal individual scrum force (269.27 ± 48.35 kg) was correlated to total body mass ($r=0.45$, $p=0.01$). Subsequent analysis of the force was standardized as the percentage force per total body mass. The force percentage was significantly correlated to the lower limb power, as measured by the vertical jump height ($r=0.40$, $p=0.03$). Separating the tight forwards into front rows and locks there was a correlation for front row player between maximal force and vertical jump power ($r=0.56$, $p=0.02$). This relationship was not present in the group of isolated locks.

A significant correlation between the change in back angle (from starting position to maximal force position) and maximal force produced was present in the combined biomechanical sample ($r=0.44$, $p=0.04$). No significant predictors were present between the right knee, left knee, right ankle, left ankle and the development of the force in the combined group of tight forwards. The isolated lock group displayed a significant correlation between the change in left knee angle and maximal force produced ($r=0.80$, $p=0.01$).

Conclusion: The study suggests that individual forces produced during scrummaging are closely related to the lower body power as determined by the vertical jump height. However lower leg power might not be a suitable test to determine the scrumagging forces in locks. Furthermore the development of the power while scrummaging can be attributed to the change in back angle and not the changing in the limb angles. However, locks when isolated, displayed a relationship between the change in left knee angle and maximal force produced. The trend for increased force values when in a more vertical position could have implications for coaches and players, regarding the limits of the laws of rugby. Furthermore by improving the strength of the lower back, surrounding musculature and lower limb power may improve scrum force development.

THREATS TO INTERNAL VALIDITY FROM STUDY DESIGNS THAT REPEATEDLY ASSESS DROP JUMP TASKS

Szu-Ting Chen [1]Yuan.Mei Sun [1]Mu.San Chang [2]I.Lin Wang [3]Li.I Wang [1,*]

[1]National Dong Hwa University, Department of Physical Education and Kinesiology, [2]Tzu Chi University, Center of Physical Education, [3]National Dong Hwa University, Department of Life Science and the Institute of Biotechnology, Hualien, Taiwan, Republic of China

Introduction and Objectives: Biomechanical research often employs drop jump tasks to investigate the effect of plyometric training [5,6]. The movement characteristic of drop jump is based on a stretch-shortening cycle (SSC). This movement produces elastic energy storage and reuse and stimulates the muscle spindles, thereby increasing muscle activity [4]. The common study design of experimental tests assessing drop jump tasks involves continuous and repeated movements [6]. However, Chen et al. (2013) indicated that the counter movement jump performance increased acutely after drop jump programs [3]. Therefore, it is uncertain whether the study design involving repeatedly testing drop jump tasks interferes with internal validity. The purpose of this study was to investigate the influence of repeatedly testing drop jump tasks.

Methods: Fifteen male college students (19.47±0.72 years, 1.73±0.04 m, and 64.67±4.89 kg) from the physical education department voluntarily participated in the study. Subjects had sustained no lower extremity injuries during the six months prior to the experiment. This study was approved by the Institutional Review Board.

Kinematic and ground reaction forces data were recorded using 8 infra-red Qualisys motion capture cameras (200 Hz) and 2 force platforms (AMTI, 60 cm×90 cm) (1000 Hz). The kinematic and kinetic data were recorded using MotionMonitor analysis software. According to the Helen Hayes marker set, 21 reflective balls required for data interception were used. The reactive strength index (RSI) was calculated using the formula: *RSI=jumping height/ground contact time* [2].

The subject repeated the drop jump task five times (T_1, T_2, T_3, T_4, T_5) from a 40 cm height platform. The rest time between tests was 1 minute.

The SPSS 14.0 statistical program was used for statistical analysis. The repeated-measures one-way ANOVA was used to assess the differences between tests. The significance level was set at α=0.05. The LSD test was used as a post hoc test.

Results: The results of this study are shown in Table 1. The jump height of T4 (P=0.048) and T5 (P=0.002) were significantly greater than T1. The jumping height of T5 was significantly greater than T2 (P=0.041). There were no significantly difference (P=0.126) in ground contact time. The RSI of T_2 (P=0.037) and T_5 (P=0.037) was significantly greater than T_1 (P=0.024).

Conclusion: Drop jump tasks are often used in exercise training research. The study design typically includes repeated testing to collect the data. However, the drop jump could acutely affect lower extremity muscle strength [3].

Jumping height [7], ground contact time [1,10], and RSI are often used to evaluate the experimental results [2]. In this study, the results indicate that the repetitive drop jump tests did not reduce the interference of the ground contact time. However, the threats to internal validity based on the study design that involves repetitive testing of drop jump tasks were

observed with regard to jump height and RSI. The jump height increased from T_4, and the RSI also increased at T_2 and T_5.

Table: Table 1 The Mean (SD) of jumping height, ground contact time, and RSI during DJ of 5 tests

	T_1	T_2	T_3	T_4	T_5	post hoc test
Normalized jumping height (BH)	0.166 (0.029)	0.173(0.033)	0.173(0.035)	0.175(0.034)	0.178(0.034)	4,5>1; 5>2
Ground contact time (sec)	0.261(0.063)	0.243(0.062)	0.255(0.073)	0.259(0.077)	0.253(0.067)	-
RSI (BH/sec)	0.655(0.136)	0.747(0.228)	0.709(0.172)	0.714(0.200)	0.738(0.210)	2,5>1

KINEMATICS ANALYSIS OF TATYANA DEKTYAREVA'S HURDLE CLEARANCE TECHNIQUE

Chia-Ling Chu [1] Yi-chun LIn [1] Chun-Ju Yang [1] Wen-Tzu Tang [1,*]

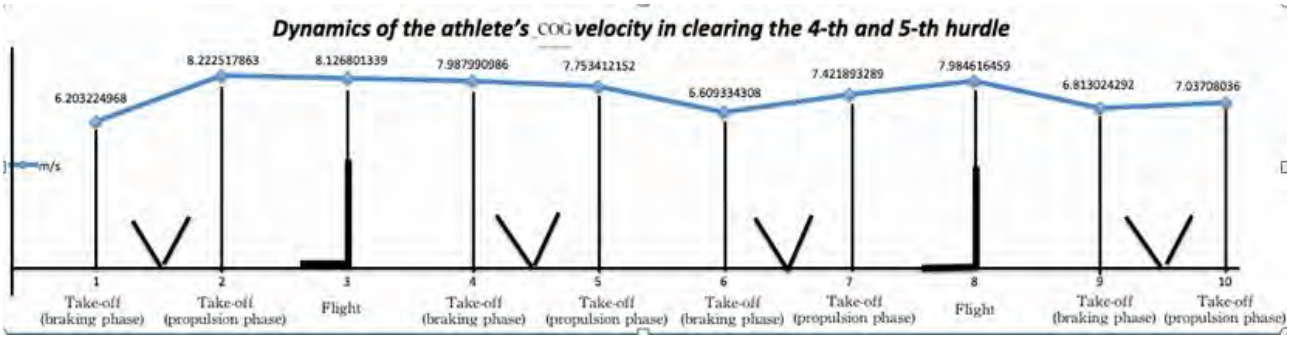
[1] Coach Science Institute, National Taiwan Sport University, Taoyuan County, Taiwan, Republic of China

Introduction and Objectives: The 100 meters Hurdles is characterised by continuous alternation between cyclical (sprint) and acyclical movements (hurdle clearance) at the highest possible speed. Previous research shows the result of man 110m hurdles of a European champion, it suggests that the horizontal velocity of the hurdler between the fourth and the fifth hurdle is highly correlated with the end result in the Hurdle race. Due to the different between the physical condition of man and woman, will the different technique exist in fourth and fifth hurdle in top European woman 100m hurdles athlete. The purpose of this study is to explore the woman European champion in 100m hurdles, the 4th and 5th hurdles during the training was analysed in following phases: take-off phase, flight phase, landing phase and run between hurdles.

Methods: The woman European champion in 100m hurdles Tatyana Dektyareva was participated in this study. The first three hurdles were removed in order to develop the optimal velocity when subject reach the 4th and the 5th hurdle. Kinematic parameters were collect by 2 casio camera with 210 frame per second, the camera were synchronized and located in the area between the fourth and fifth hurdle. The film was digitized through Direct Linear Transformation method in Kwon3D motion analysis system and the center of gravity was derived with a 12-segment model (Z1-Zatsiorsky, 1983).

Results: Between 4th and 5th hurdle, the horizontal velocity of the center of gravity(COG) in the braking phase is 6.20m/s, while in the propulsion phase it increases to 8.13m/s, which has increase 23.5% and the vertical velocity is 1.23 m/s. It shows the efficiency to accelerate the velocity during take-off. The horizontal and vertical velocities define the elevation velocity of the COG, which is in this case is 8.20 m/s. The relationship between horizontal and vertical velocities shows the athlete's ability for an efficient transition from the running stride into the take-off stride. The landing phase has the largest reserve potential for improving the competition result. The result shows the horizontal velocity of the COG in the landing phase is 7.92m/s, which means it only decrease 0.21m/s during the hurdle clearance phase. Less reduction of horizontal velocity during 4th and 5th hurdle during this training shows the efficient and less energy loss during the movement.

Figure:



Caption: Figure 1 Dynamics of the athlete's COG velocity in clearing the 4th and 5th hurdle

Conclusion: Great energy transition during horizontal and vertical velocities at take-off phase and less velocity reduction during clearance phase was found during this study, it shows the advantage of this training method that encourage the athlete to reach the peak velocity at 4th hurdle and perform the hurdle technique.

Table: Each phases of athlete's COG velocity in Hurdle clearance

	Take-off (braking phase)	Take-off (propulsion)	Flight	Landing (braking phase)	Landing (propulsion phase)
Vx of COG	6.2m/s	8.13m/s	8m/s	7.92m/s	7.75m/s
Vy of COG	-0.2m/s	1.23m/s	1.42m/s	-1.04m/s	-0.23m/s
Vt of COG	6.2 m/s	8.2 m/s	8.1 m/s	7.9 m/s	7.7 m/s

* Vx of COG is Horizontal velocity of COG; Vy of COG is Vertical velocity of COG; Vt of COG is Velocity resultant of COG.

Caption: Table 1 Each phases of athlete's COG velocity in Hurdle clearance

DOES RUNNING TECHNIQUE ALTER MUSCLE ACTIVATION PATTERN IN HEALTHY RUNNERS?

Ana F. dos Santos [1,*] Theresa H. Nakagawa [1] Giovana Y. Nakashima [2] Carlos D. Maciel [2] Fábio V. Serrão [1]

[1]Department of Physical Therapy, Federal University of São Carlos, [2]Department of Electrical Engineering, University of São Paulo, São Carlos, Brazil

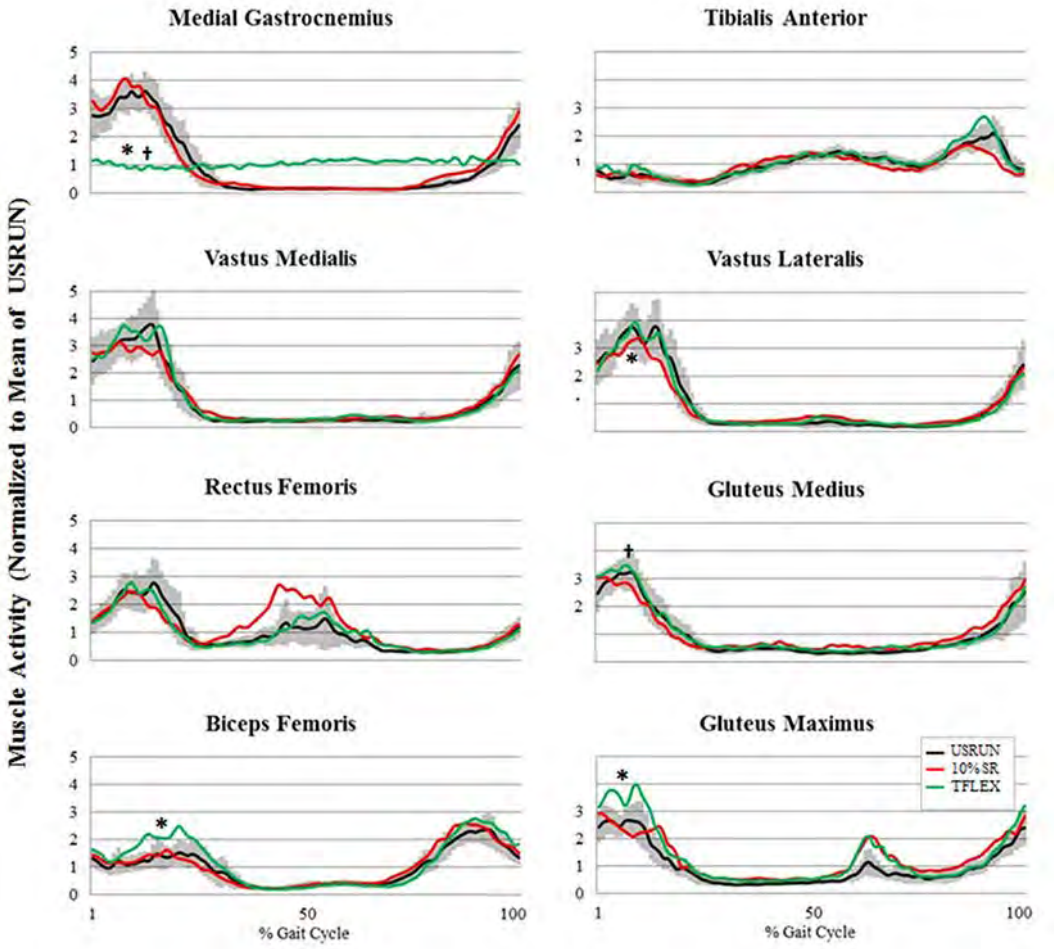
Introduction and Objectives: The growing number of running practitioners has been noticed all over the world. In Brazil, it is estimated a 30-fold increase in the number of runners in the last 15 years [1]. However, this practice has a potential risk for injury. It is known that most of the injuries that occur during this activity is related to the knee joint (42%) being patellofemoral pain the commonest one [2]. Recently, running with increased step rate and trunk flexion showed potential to reduce the knee joint demand and the patelofemoral joint stress [3,4]. It is important to investigate the effect of different running techniques on lower limb biomechanics in order to improve injury prevention and rehabilitation programs. In particular, it is necessary to understand the hip, knee and ankle muscle activation pattern.The purpose of this study was to compare the lower limb neuromuscular activity pattern among usual, increasing 10% step rate (10%SR) and increasing trunk flexion (TFLEX) running techniques.

Methods: Twenty healthy recreational runners (5 females, 15 males) participated in the current study. All subjects ran a minimum of 20 km/week for at least 3 months and presented a rearfoot strike pattern during running. Each subject completed a familiarization session (3 days before) when it was determined the preferred speed (9.7±1.4 km/h) and step rate (166.8±7.2 steps per min). The runners performed usual (USRUN) plus the two running techniques at a random order on a treadmill. For the 10%SR technique, they were monitored using a metronome. The TFLEX technique was verbally stimulated and visually confirmed. The electromyographic signal (EMG) of medial gastrocnemius (GASTRO), tibialis anterior (TA), vastus medialis (VM) and lateralis (VL), rectus femoris (RF), gluteus medius (GMED), biceps femoris (BF) and gluteus maximus (GMAX) were recorded at 2400 Hz, detected using 8 wireless surface EMG electrodes (Trigno™ Wireless System). The EMG signals were processed using custom MATLAB software. Raw EMG data were band-pass filtered (20-450 Hz, 4^{th}-order Butterworth), full-wave rectified and smoothed using a 50-Hz low-pass filter (bidirectional, 6^{th}-order Butterworth). The average of 10 stance phases of each condition from the dominant lower limb was analyzed. The mean EMG activity was normalized by the average of total gait cycle. The stance phase was defined from the minimum vertical position of the distal heel marker to the second knee extension peak. The MANOVA with repeated measures was used for analysis (alpha set at 0.05).

Results: This was the first study to compare lower limb neuromuscular activation during USRUN, 10%SR and TFLEX running techniques. The TFLEX technique showed greater differences at the average EMG curves (Fig 1 and Table 1). As expected, the 6.5º increase in trunk flexion angle resulted in greater hip extensors muscle activation during stance phase when compared to USRUN. We observed 38% increase in BF and 46% increase in GMAX activity; while GASTRO activation decreased 57%. At 10%SR technique, the VL EMG data showed 12% lower activation when compared to USRUN. Greater GMED and lower GASTRO activity during TFLEX was found when compared to 10%SR.

Previous studies have demonstrated beneficial effects of both running techniques on the knee joint [3,4]. However, each technique showed distinct biomechanics adaptation. In the current study, we showed greater activation of the proximal joints and lower demand on the distal joints during TFLEX. To the best of the authors' knowledge, this was the first study to report these results. Contrary to Chumanov et al. [5] at 10%SR, it was observed a reduction in knee extensor muscle activation during the stance phase. These results could be related to diminished knee extensor moment and consequently less patellofemoral joint stress. In addition, TFLEX, as compared to 10%SR, showed greater GMED activation, allowing greater frontal plane hip movement control potentially preventing detrimental effects on the patellofemoral joint.

Figure:



Caption: Mean muscle activities during the gait cycle. The gray shaded regions represent the USRUN EMG (mean ± 0.5 SD).

Conclusion: The 10%SR and TFLEX showed different lower limb muscular activation pattern; which could potentially reduce knee injury risk. These information may improve the physical therapists understanding of the effects of different running techniques, to better prescribe running techniques in the prevention and rehabilitation programs.

Table: Mean of muscle activity during stance phase of running.

	USRUN	10% SR	TFLEX

KINEMATIC ANALYSIS OF THE SPEED MAINTENANCE PHASE OF 100 M RUNNING

Emel Cetin [1,*] Ethem Hindistan [1] Suleyman Akay [1]

[1] School of Physical Education and Sports, Akdeniz University, Antalya, Turkey

Introduction and Objectives: The speed profile is used to subdivide the 100m sprint performance into 4 phases: a start action, an acceleration phase, a phase of maximal sprint and a deceleration phase (1). Successful sprint running performance requires good starting ability, highest maximum running speed, and endurance of that speed capacity. Maximum running velocity in elite sprinters is achieved by optimal stride length (SL) and stride frequency (SF) in the distance between 30 m and 60m. Generally shorter contact time (CT) results in greater performances in sprinting; therefore, faster sprinters have shorter contact time than slower sprinters in each stride (2). Therefore, the longer speed maintenance phase will play an important role in improving the performance. The aim of the study was to evaluate further the effects of 8 week of training on the stride characteristics at speed maintenance phase of 100 m sprint running performance.

Methods: A total of fourteen male sport and physical education students (Training Group: age 19.57±1.13 years, weight 67.49±6.37 kg, height 174.86±4.34 cm; Control Group: age 21.57±1.13 years, weight 67.27±3.79 kg, height 177.86±4.34 cm) participated in this study. After completion of a 20-min warm-up, Training Group performed 12x25 m sprints at maximal intensity. Active rest was applied between sprint repetition (2.5 min) and sets (5 min). In the 5^{th} and 6^{th} week and in the 7^{th} and 8^{th} week of the training program one repetition was added at first- third and second-forth set, respectivelly. Five video cameras (Basler piA640- 210 Hz) were used to collect stride parameters recordings of the sagittal plane of between 50m-100m interval of running performance. Photocells were used to assess sprinting performance (t) and the 10 m time splits of the participants. Two-Related Samples test was used to establish if there were any significant differences between trials (pre-post). The significance level for the tests was set at $p<.05$.

Results: After 8 week sprint training, training group produced increases in running performance by 2.4 %. Working group achieved the maximum speed of running at 60m-70m interval and 50m-60m interval, pre and post training respectively. There is significant changing for stride length and stride frequency at 70m-100m interval. Compared to the pre-training at this interval, decreased stride length increased stride frequency.

Conclusion: If the 100 m sprint performance of training group is compared to the running performance for pre-post 8 week training, training group produced increases in running performance by 2.4 %. Dintiman, after 8 weeks of horizontal training, observed an improvement of 5.2% in performance for 50 m, and Suellentrop found a 2.5% improvement in 100 m performance after 6 weeks of training(3). The elite sprinters commonly achieve the maximum speed of running 50-60m interval (M.Green, D.Chambers, T. Montgomery et al.), 40-60m interval (B.Surin), or 50-70m interval (O. Thompson, K. Streete-Thompson) (4), whereas the investigated group achieved at 60-70m and 50-60m intervals, pre-post training respectively (Table 1). After 8 week training program, despite the fact that group have finished the running performance with their maximum running speed 93.72% , there were significant differences for SL and SF in last 30 m.

In this study, there is no significant improvement in RS at 60-100 m interval. However, SL showed significantly decrease 10.12% and 5.8% in this interval pre-post training, respectively. In proportion to SL, SF showed significantly increase 6.48% and 1.25 %, respectively.This indicates that the increase in performance resulted from the arrangements between SL and SF.

TECHNIQUE COMPARISON OF MALE AND FEMALE HAMMER THROWERS

Suzanne Konz [1,*] Iain Hunter [2]

[1]Kinesiology, Marshall University, Huntington, WV, [2]Brigham Young Unviersity, Provo, UT, United States

Introduction and Objectives: Distinct anthropometric differences occur between the sexes throwing the hammer that likely affect optimal technique. The scientific literature has focused predominately on the characteristics of male hammer throwers. No literature statistically compares the differences between the throwing technique of male and female hammer throwers. The aim of this study was to determine what the hammer throwing technique differences, if any, occur between genders.

Methods: The performances of the top 16 male and female throwers at the 2003 World Athletic Final and the top 13 male and female throwers from the 2003 USA Track and Field Nationals were examined. Video was captured using three Canon 60 Hz cameras. The best throw of each athlete was digitized and analyzed using the Peak Motus 8.2 motion analysis system.

Results: ANOVA (see Table 1.) revealed that athlete mass, athlete height, velocity at release, timing components, and centripetal force were different between sexes. The methods used to obtain greater performances also varied slightly between sexes.

Conclusion: The general movement and technique for male and female throwers is similar. However, there are certain characteristics that vary to some degree between sexes. Coaches and athletes should be aware of these differences to help athletes progress towards optimal technique between sexes.

Table:

	Men (n=14)		Female (n=15)		
Variable	Mean	SD	Mean	SD	*p* value
Athlete Mass (kg)	112.9	13	86.7	12.89	<0.001

PO-0381

CHARACTERISTICS IN CENTER OF PRESSURE TRAJECTORY DURING WALKING IN SPRINTERS

Yu Kashiwagi [1,*] Tomoya Hirano [2] Noriko Hakamada [3] Kazuo Funato [2] Tadashi Wada [4] Masuhiko Mizuno [2]

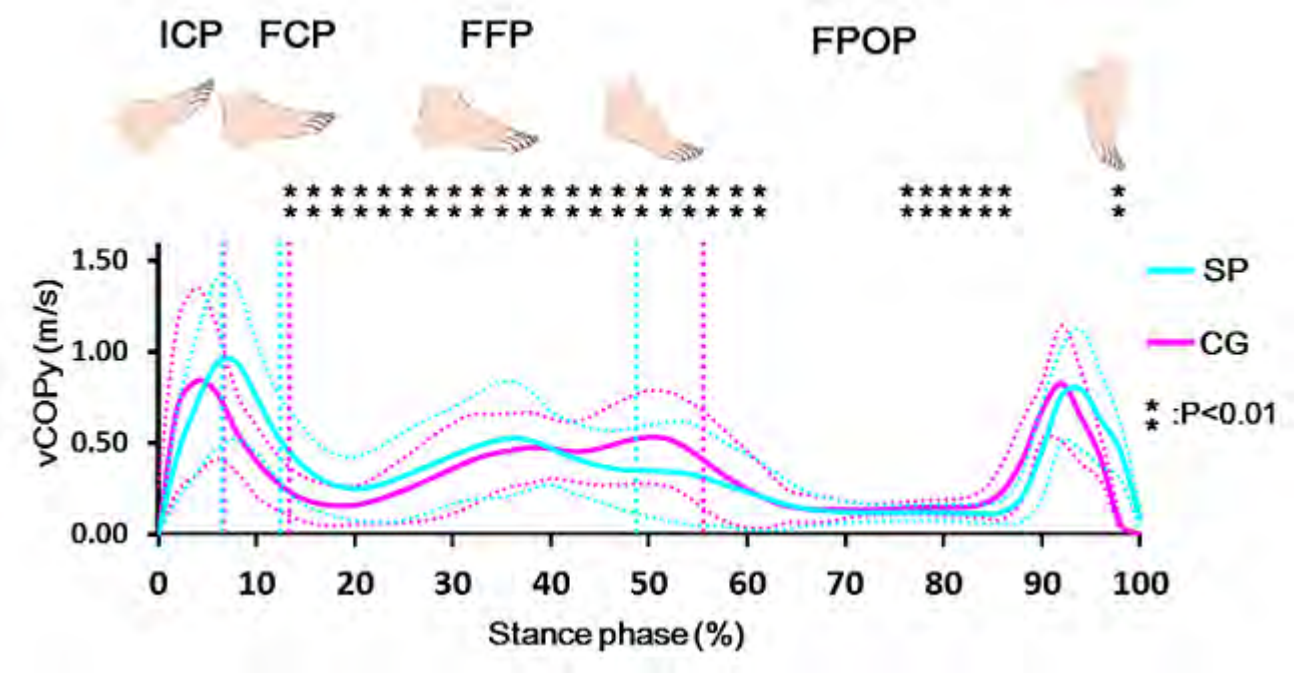
[1]Graduate school of Health and Sport Science Nippon sport science university, [2]Nippon sport science university, [3]Japan institute of sports sciences, [4]Kokushikan university, Tokyo, Japan

Introduction and Objectives: Center of pressure (COP) trajectory can provide useful information in assessing the foot function and gait pattern[1]. It is not clear however, whether a sprinter can get an effective gait pattern by prolonger sprint training. The purpose of this study was to investigate the characteristic of COP trajectory during walking in sprinters. Hypothesis was considered sprint training would influence of displacement of effective COP trajectory during stance phase in walking.

Methods: Nineteen male college sprinter (SP; Age:19.9±0.9yrs, BH:174.1±5.4cm, BW:64.9±14.2kg, 100m sprint time:11.10±0.3sec) and fifteen male healthy young adults (CG; Age:20.5±2.3yrs, BH:172.6±5.8cm, BW:64.1±9.9kg) participated in this study. Subjects were asked to walk five times along the walkway at self selected walking pace. A dynamic pressure measurement system (footscan system RSscan International Belgium) was used to record the COP coordinates, velocity and progression angle. All data were recorded at measurement frequency of 500Hz and processed using scientific footscan software. Actual walking speed was measured using photo-cells set at interval of 5m in walkway. Spatio-temporal parameters were calculated from gait cycle time using high speed camera (240fps, JVC GC-P100, Tokyo, Japan). Stance phase was divided into four sub-phases; Initial contacts phase (ICP), Forefoot contact phase (FFCP), Foot flat phase (FFP), Forefoot push off phase (FFPOP). Arch index was assessed as preliminary research by Cavanagh RJ. (1987) [2] from foot pressure prints during stance phase. All statistical analysis were used by student's t-test (welch) performed on selected means to detect significant differences (effective $P < 0.05$) between SP and CG (JMP ver. 8.0 : SAS inc.).

Results: Foot arch index and spatio-temporal parameters were not different between SP and CG. In % FFP time, SP(35.3±10%) was shorter than CG(43.1±7.3%, $P<0.05$). On the other hand, %FFPOP time indicated longer in SP than CG (SP:51.3±10.5% vs CG:44.5±6.5%, $P<0.05$). Liner COP trajectory pattern of SP from heel to the second metatarsal was observed compared with CG. Thereafter COP shifted to medial side from the second metatarsal to hullx before toe-off in both SP and CG. Anterior-posterior COP velocity was larger in SP than CG during early FFP(12~33% of stance time, $P<0.01$, Fig.1). Larger COP velocity of FFP in SP might be considered as strategy so as to get smooth center of mass trajectory to anterior direction and also enable to get a large %FFOP in order to accelerate the body.

Figure:



Caption: Velocity of center of pressure in anterior-posterior direction (vCOP, mean±SD) during normalized stance phase for sprinter(SP) and health young subjects(CG). Vertical dashed line divide four stance phase; ICP: Initial contacts phase, FFCP: Forefoot contact phase, FFP; Foot flat phase, FFPOP; Forefoot push off phase.

Conclusion: COP velocity in front direction during early period of Foot flat phase was larger in sprinter, as well as an effective COP trajectory pattern in Foot push off phase. These characteristics might play an important role for increasing the propulsive time transferred from hullx. This study suggests effective COP trajectory in sprinter might be results from sprint training so as to move center of mass more smoothly.

PO-0382

GENDER COMPARISON OF ANTAGONISTIC MUSCLE ACTIVITY DURING ISOKINETIC TRUNK EXTENSION

Lucie Risch [1,*] Stephan Kopinski [1] Monique Wochatz [1] Martin Wolter [1] Steffen Mueller [1] Frank Mayer [1]

[1] Sports & Health Science , University Outpatient Clinic Potsdam, Potsdam, Germany

Introduction and Objectives: It is well known that healthy males and females differ in absolute strength values. However, evidence for gender differences in muscle activity measured with surface EMG during trunk exercises show conflicting results. Females were observed recently to have higher relative agonistic trunk muscle activity during submaximal isokinetic trunk extension compared to males. If a simultaneously higher antagonistic activity for stabilization of the spine is an influencing factor for this finding is not clear. Therefore, the aim of this study was to investigate if abdominal antagonistic activity differs between healthy males and females during maximal and submaximal isokinetic trunk extension tasks.

Methods: Fifty healthy participants (25 males: 28±4 yrs, 78±8 kg, 1.82±0.06 m; 25 females: 25±3 yrs, 60±7 kg, 1.67±0.06 m) with no history of low back pain were prepared with a 6-lead bilateral surface EMG (myon RFTD-32, myon AG, Suisse) setup (M. erector spinae: L3 and Th9; M. rectus abdominis) and performed maximal and submaximal strength tests in an isokinetic trunk dynamometer (Con-Trex MJ,TP-module, Physiomed AG, Germany). Trunk motion ranged from 45° flexion to 10° extension with a movement velocity of 45°/s. After warm-up, participants completed 5 maximum voluntary contractions (MVC) in trunk extension (MVCext) and flexion (MVCflex) followed by 4 submaximal extension tests (subMVC) at 20, 40, 60, and 80% of MVCext with 5 repetitions each. Outcome measure was the root mean square (RMS) of abdominal antagonistic muscle activity during extension normalized to RMS of abdominal agonistic activity during MVCflex. Data was analysed descriptively presenting mean±SD. Mann Whitney U-test was used to test for significant differences between genders. A repeated measures ANOVA was calculated to test for an interaction effect between gender and tasks. Significance level was set at α=0.05.

Results: Absolute extension and flexion torques were significantly higher ($p<0.001$) in males (MVCext: 317±63 Nm, MVCflex: 201±47 Nm) than in females (MVCext: 214±55 Nm, MVCflex: 126±26 Nm). Regarding abdominal antagonistic activity, females have higher activation compared to males during all tasks showing significant difference at 60% of torque production (see Tab. 1). No statistical significant interaction effect between genders was found ($p=0.78$).

Figure:

Gender	20% of MVC	40% of MVC	60% of MVC	80% of MVC	100% of MVC
Female	4.1 ± 3.6	3.7 ± 2.1	4.4 ± 2.4	5.6 ± 2.9	7.7 ± 4.0
Male	2.9 ± 1.9	2.9 ± 1.8	3.2 ± 2.0	4.2 ± 2.5	6.6 ± 4.5
P-Value	0.114	0.109	*0.047	0.076	0.177

*indicates p<0.05

Caption: Abdominal antagonistic activity [%, mean±SD]

Conclusion: Antagonistic activity rises with increasing torque production in both genders. Generally, antagonistic activity level relative to MVCflex is low. It is assumed that the higher antagonistic muscle activity in females might increase spinal stabilisation and may be related to the higher relative agonistic activity recently found during isokinetic extension.

SCAPULOHUMERAL RHYTHM DURING ARM ELEVATION IN PATIENTS WITH ACROMIOCLAVICULAR OSTEOARTHRITIS

Catarina O. Sousa [1,*] Paula Camargo [2] Lori Michener [3] Ivana Ribeiro [2] Rodrigo Reiff [4] Tania Salvini [2]

[1]Department of Physical Therapy, Federal University of Rio Grande do Norte, Natal - RN, [2]Department of Physical Therapy, Federal University of São Carlos, São Carlos, Brazil, [3]Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, United States, [4]Department of Medicine, Federal University of São Carlos, São Carlos, Brazil

Introduction and Objectives: The acromioclavicular (AC) joint is a common source of shoulder pain. Cartilaginous degeneration can occur from the high axial loads transferred through the small and incongruent joint surface area during complex torsional movements during shoulder movements, leading to osteoarthritis [1]. A clinical parameter heavily affected in most shoulder disorders is the scapulohumeral rhythm (SHR) [2], which is the relationship between elevation at the glenohumeral joint and scapular upward rotation [3]. The SHR provides an important parameter to characterize shoulder function during dynamic activity [4].

Considering the lack of studies on this topic in patients with AC osteoarthritis (ACO), the purpose of this study was to describe the SHR during arm elevation (ascending and descending phases) in individuals with isolated ACO and to compare to healthy asymptomatic subjects.

Methods: The study included 49 individuals: 23 with ACO (15 men, 8 women; 42.78±11.74 years; 75.21±14.17 kg; 1.72±0.12 m); and 26 asymptomatic healthy subjects (13 men, 13 women; 45.81±8.68 years; 66.27±9.32 kg; 1.66±0.08 m). Scapular motion was collected with an electromagnetic tracking system (Flock of Birds) during elevation of the arm. The sensors were attached to the sternum, acromion of the scapula, and to a thermoplastic cuff secured to the distal humerus to track humeral motion. Anatomical coordinate systems were established for each segment by palpating and digitizing anatomical landmarks as per the International Society of Biomechanics recommended protocol [5]. The individuals completed 3 repetitions of arm elevation in the sagittal plane guided by a flat plane surface. The symptomatic shoulder was evaluated in subjects with ACO, and the shoulder for the asymptomatic healthy subjects was randomly chosen. The SHR was calculated as the ration of elevation on glenohumeral joint to upward/downward rotation on scapulothoracic joint for each trial of arm elevation with 30º of increment of humeral elevation during ascending (30º-60º, 60º-90º, 90º-120º) and descending phases (120º -90º, 90º-60º, 60º-30º), and then averaged across the three trials for data analysis.

SHR was analyzed with a separate linear mixed-model 2-way ANOVA for each phase (ascending and descending), in separate, using intervals of humeral elevation as the repeated factor and groups as the main factor. Comparisons of interest were the interactions of group by intervals of humeral elevation, or main effect (groups). The significance level of 5% was adopted.

Results: No interactions of group by intervals of humeral elevation were found for SHR in either phase of arm elevation (ascending and descending). Considering main effect factor, during ascending phase, there was difference between

groups (P= 0.01) which individuals with ACO presented lesser SHR compared to asymptomatic healthy subjects (mean difference = 0.59). During descending phase, no difference was found.

The smallest value of SHR in subjects with ACO, during ascending phase of arm elevation, must be related to greater scapular upward rotation in these subjects [6]. Scapular upward rotation is significantly increased in patients with many types of shoulder disorders [7], which may represent compensatory responses for an attempt to reduce pain during the arm elevation.

Conclusion: Individuals with ACO showed decreased SHR during the ascending phase of arm elevation compared to asymptomatic healthy subjects. These alterations may be related to an increased scapular upward rotation which may represent compensatory responses as an attempt to reduce pain in subjects with ACO. Future studies are needed, especially to verify if these alterations are associated to changes in muscle activation.

INTER-SESSION RELIABILITY OF SCAPULAR MUSCLE ACTIVITY DURING ISOKINETIC TESTING OF SHOULDER FLEXION AND EXTENSION IN THE SCAPULA PLANE

Monique Wochatz [1,*] Sophie Rabe [1] Martin Wolter [1] Stephan Kopinski [1] Steffen Mueller [1] Frank Mayer [1]

[1]Department Sports & Health Sciences, University Outpatient Clinic Potsdam, Potsdam, Germany

Introduction and Objectives: Overhead athletes frequently suffer from shoulder complaints. Isokinetic dynamometry is commonly used to assess muscle performance in healthy and injured populations. Additional EMG application offers the possibility to investigate neuromuscular performance in different standardized measurement conditions involving motions typical for overhead sports. Previous studies could show an association between shoulder pathologies and altered scapular muscle activity pattern. Detected differences in the scapular muscle activity level were shown to vary between 4% and 25% between healthy and injured individuals. However, data of measurement accuracy of scapular muscle EMG during isokinetic overhead motion is rare and thus limits the interpretation of detected group differences. Therefore, this study aimed to evaluate the inter-session variability of scapular muscle activity during isokinetic testing in asymptomatic individuals.

Methods: Eleven asymptomatic participants (29±2 yrs; 1.72±0.09 m; 73±15 kg) underwent isokinetic testing (Con-Trex, WS, Physiomed AG Germany) of the dominant arm twice (M1 and M2) separated by at least 5 days. Simultaneously muscle activity of the upper (UT) and lower trapezius (LT) and serratus anterior (SER) was assessed by a 3-lead surface EMG (myon RFTD-32, myon AG, Suisse). Isokinetic testing was conducted in a standing position and comprised shoulder flexion and extension in scapula plane in the following modes: concentric with 60 (CON_{60}) and 180°/s (CON_{180}) and eccentric with 60°/s (ECC). Range of motion (ROM) was set to 160° ranging from 20° to 180° of shoulder flexion. After a warm up participants executed 5 repetitions with maximum effort for each condition. EMG activity of shoulder flexion and extension quantified over the whole ROM by Root Mean Square (V, mean±SD) was averaged over the 5 repetitions and normalized to muscle activity of CON_{60} condition [%]. To evaluate the reliability test-retest variability (TRV, %), intra-class correlation coefficient (ICC, 2.1), Bias and 95% limits of agreement (LoA, Bias±1.96*SD) were calculated.

Results: Absolute EMG activity of reference condition CON_{60} ranged from 0.43 V to 0.90 V. Normalized mean muscle activity for CON_{180} and ECC of shoulder flexion ranged from 81±12% to 115±11%. During shoulder extension of CON_{180} and ECC mean muscle activity varied from 14±11% to 31±16% between LT, UT and SER. Across all conditions and muscles ICC varied between 0.37 (extension, ECC, SER) and 0.93 (extension, CON_{180}, UT) and TRV ranged from 8.6±4.6% (flexion, ECC, SER) to 30.4±27.4% (extension, CON_{180}, LT). The Bland-Altman analysis revealed a systematic error from -6.2% with LoA of 6.6 and -6.1% (flexion, CON_{180}, LT) to an error of 4.1% with LoA of 28.9 and -20.8% (extension, ECC, LT) (Table 1).

Figure:

Condition			M1	M2	ICC	TRV [%]	Bias	LoA
			mean±SD	mean±SD		mean±SD		
Flexion	CON_{180}	LT	105 ± 23	111 ± 24	0.80	9.8 ± 8.5	-6.2	20.2; -32.5
		UT	109 ± 15	115 ± 11	0.57	9.6 ± 7.3	-6.0	15.6; -27.7
		SER	90 ± 12	91 ± 14	0.71	8.0 ± 5.7	-1.3	17.1; -19.6
	ECC	LT	82 ± 11	84 ± 13	0.74	9.0 ± 6.6	-1.6	15.3; -18.6
		UT	82 ± 14	81 ± 12	0.67	10.0 ± 9.3	0.9	20.6; -18.7
		SER	85 ± 20	83 ± 18	0.92	8.6 ± 4.6	2.2	16.7; -12.3
Extension	CON_{180}	LT	22 ± 10	20 ± 6	0.79	14.6 ± 13.0	2.2	12.2; -7.8
		UT	14 ± 11	15 ± 9	0.93	24.4 ± 16.9	-1.5	5.7; -8.7
		SER	26 ± 8	27 ± 8	0.69	21.1 ± 12.2	-1.7	9.9; -13.3
	ECC	LT	31 ± 16	26 ± 12	0.55	30.4 ± 27.4	4.1	28.9; -20.8
		UT	20 ± 7	21 ± 6	0.73	23.1 ± 21.8	-1.0	8.0; -10.1
		SER	24 ± 8	25 ± 6	0.37	21.6 ± 15.8	-1.1	13.6; -15.9

Caption: Table 1: Normalized EMG activity (% MVC CON60) of scapula muscles for M1 and M2 (mean±SD) and associated reliability measures.

Conclusion: The level of agreement of scapula muscle activity between the measurements varied across conditions and muscles from moderate to good reliability. Only SER showed high variability during shoulder extension ECC. Due to smaller scapula muscle activity levels during isokinetic shoulder extension possible group differences might be masked by the measurement variability. Concentric and eccentric isokinetic conditions during shoulder flexion seem the more feasible settings to assess differences or changes in scapular muscle activity between healthy and symptomatic athletes.

TEMPLATE-MATCHING IN THE IDENTIFICATION OF ARM-HAND SKILL PERFORMANCE IN HEALTHY SUBJECTS AND STROKE PATIENTS

Ryanne Lemmens [1,*] Yvonne Janssen-Potten [2] Annick Timmermans [3] Rob Smeets [1] Henk Seelen [2]

[1]Rehabilitation Medicine, Research school CAPHRI, Maastricht University, Maastricht, [2]Adelante Centre of Experise in Rehabilitation and Audiology, Adelante Rehabilitation Centre, Hoensbroek, Netherlands, [3]BIOMED, Biomedical Research Institute, Hasselt, Belgium

Introduction and Objectives: Objectively assessing actual arm-hand skill performance (AHSP) is very important to evaluate therapy efficacy in patients with neurological disorders. Instruments to identify skills and determine both amount and quality of actual AHSP in daily life are lacking, necessitating the development of a new measure. To identify skills, pattern recognition techniques like statistical classification, neural networks, structural matching and template matching can be used. The aim of this study is to provide proof-of-principle of a method to identify activities based on template-matching, in a healthy participant and a patient with stroke.

Methods: Multiple devices, each containing a tri-axial accelerometer, tri-axial gyroscope and tri-axial magnetometer were attached to the hand, wrist, upper arm and chest of participants, i.e. four devices to the dominant arm-hand and chest of the healthy participants, and seven devices to both arms and hands and the chest of the stroke patient. Thirty healthy individuals and one patient with stroke performed the activities ‘drinking’, ‘eating’ and ‘combing’ 5 times in a standardized manner, i.e. with similar starting position and instruction on how to perform the skill. Signals were filtered with a 4th order zero-time lag low-pass Butterworth filter (cut off freq.: 2.5 Hz). Data analysis consisted of the following steps: 1) temporal delimitation of each of the five activity attempts, i.e. identifying the start and endpoint of each attempt recorded; 2) signal normalization in the time domain to correct for (small) variations due to differences in speed of task execution; 3) averaging signal matrices from the five attempts of each individual person to obtain an individual template, i.e. the underlying ensemble averaged signal matrix per task per individual; averaging signal matrices from the individual templates of the first 29 healthy persons included, to create a generic template, to identify this activity among the signals of the 30th person; 4) identification of dominant sub phases of templates, within a specific task, using Gaussian-based linear envelope decomposition procedures; 5) recognition of specific activity execution among various activities performed daily, i.e. searching for template occurrence among signal recordings gathered in a standardized setting, using feature extraction and pattern recognition algorithms based on 2D convolution. Templates representing a complete activity as well as templates containing sub phases of an activity were used. Cross-correlation coefficients were calculated to quantify goodness-of-fit.

Results: Performance of the activities ‘drinking,’ ‘eating’ and ‘combing’ were recognized with high sensitivity and high specificity in healthy participants for both the generic template and the individual template. Using the individual template, recognition occurred with high correlations (e.g. for the activity drinking a correlation of 0.93 for the template representing the complete activity and for the template containing activity sub phases mean correlations ranged between 0.89 and 0.99). Using the generic template, recognition was similar regarding sensitivity and specificity (i.e. all activity

performances were recognized) but correlations were lower (table 1). In the stroke patient performance of the activities drinking, eating and combing were unambiguously recognized using the individual template. For both the template representing the complete activity and the template containing the activity sub phases, correlations with which the activity was recognized were high (table 1). In stroke no generic template was created since only one patient was included.

Conclusion: Proof-of-concept of this method to identify a specific activity among multiple activities performed in a standardized setting was shown for both healthy participants and a stroke patient. The long-term aim is to use this method to a) identify which arm-hand skills are performed during daily life by individuals, b) determine the quantity of skill execution, i.e. amount of use, and c) determine the quality of AHSP. At the moment, as far as we know, no such instrument is available. Future research will focus on: a) optimizing the method described, and b) applying this method for more activities, in more neurological patients and in daily life situations.

Table:

		## of times an activity was:		Correlation:	
		Performed	Recognized	Complete activity	Activity sub phases
Healthy subjects	Drinking	5	5	0.79*	0.78-0.86*
	Eating	5	5	0.58*	0.69-0.80*
	Combing	5	5	0.42*	0.68-0.90*
Stroke patient	Drinking	4	4	0.99	0.81-0.99
	Eating	5	5	0.65	0.81-0.98
	Combing	4	4	0.97	0.60-0.99

*correlation based on a generic template.

RELIABILITY OF REGISTRATIONS OF DAILY LIFE ACTIVITIES MONITORED WITH MULTIPLE BODY WORN SENSORS

Ryanne Lemmens [1,*] Henk Seelen [2] Yvonne Janssen-Potten [2] Annick Timmermans [3] Marlous Schnackers [2] Richard Geers [2] Rob Smeets [1]

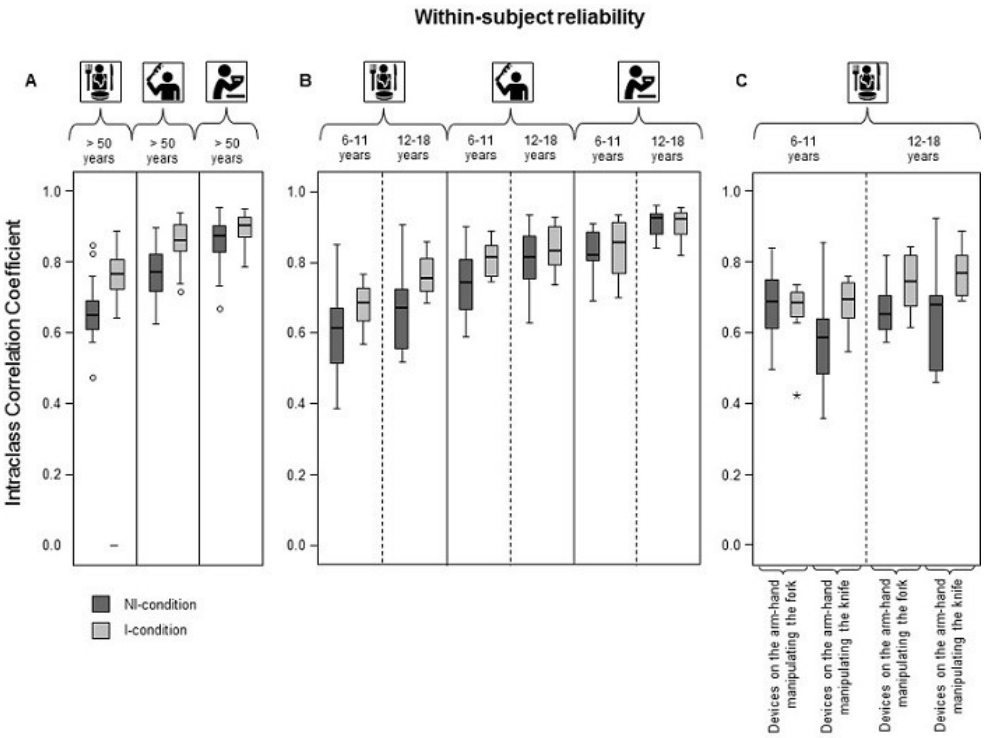
[1]Rehabilitation Medicine, Research School CAPHRI, Maastricht University, Maastricht, [2]Adelante Centre of Expertise in Rehabilitation and Audiology, Adelante Rehabilitation Centre, Hoensbroek, Netherlands, [3]BIOMED , Biomedical Research Institute, Hasselt, Belgium

Introduction and Objectives: Stroke patients or (children with) cerebral palsy often encounter arm-hand problems in daily life, assessment of which is important. Whereas many instruments are available to assess capacity or perceived performance, tools gauging actual skill performance are scarce (Lemmens et al., 2012). Body worn sensors quantifying specific movement patterns associated with specific activities may be used to assess actual performance. However, signal reliability during execution of activities of daily living should be determined first.
Aim of this study is to determine to what extent standardized arm-hand skill performance of both healthy adults and children can be recorded reliably using multiple body worn sensors.

Methods: Thirty healthy adults (aged > 50years, 14 women, 16 men, mean age 58.0 ± 5.1 years) and 32 healthy children, i.e. 16 aged between 6-11 years (9 girls, 7 boys, mean age 8.5 ± 1.7 year) and 16 aged between 12-18 years (8 girls, 8 boys, mean age 14.6 ± 1.5 years) performed the activities ‘drinking’, ‘eating’ and ‘combing’ 5 times in a standardized setting. Tasks were first performed without, and subsequently with extensive instructions on how to perform the task. Sensor devices, each containing a triaxial accelerometer, gyroscope and magnetometer were attached to the arms, hands and trunk, i.e. four devices to the dominant arm-hand and chest of the adults and seven devices to both arms and hands and the chest of the children. Signals were filtered with a 4^{th} order zero-time lag low-pass Butterworth filter (cut off freq.: 1.28 Hz). Repetitions of each specific task were identified and intra-class correlation coefficients (ICC) for each sensor and signal type were determined as a measure of reliability, both within and between subjects. For every person, a mean ICC was calculated. Boxplots of the results are presented (Fig. 1). The ICCs were classified as very good (0.8-1.0); good (0.6-0.8); moderate (0.4-0.6); fair (0.2-0.4) and slight (<0.2).

Results: As to within-subject reliability (Fig. 1), the median ICC’s were good to very good for all activities. Reliability was better in the instruction conditions than in the no-instruction conditions, especially for the skill eating. Children aged between 12-18 years showed a slightly higher reliability compared to children aged between 6-12 years.
Between-subject reliability was also good to very good for all activities performed by adults. The activity drinking performed by the children had a very good reliability, the activity combing had a good reliability whereas the activity eating had a fair to moderate reliability in the youngest children, and a good reliability in the older children. Especially for the skill eating, a large difference in reliability was seen between the instruction and no-instruction conditions. For the activities drinking and combing, reliability was comparable between younger and older children. For the skill eating, reliability was higher in the older children.

Figure:



Caption: Figure 1: Within-subject reliability (ICCs) for the activities ‘eating’, ‘combing’ and ‘drinking’. Dark grey bars: task performance without instruction. Light grey bars: task performance with instruction. A) performance by adults, boxplots representing the devices on the chest and arm-hand manipulating the knife, comb and cup; B) performance by children, boxplots representing the devices on the chest and arm-hand manipulating the knife, comb and cup; C) performance by children, boxplots representing the devices on each arm-hand.

Conclusion: Overall, the activities drinking, eating and combing had a good to very good within-subject reliability in both adults and children. By giving instructions about how to perform the task, the variability in execution of the task was reduced, thereby increasing reliability.The performance of the skill drinking had a higher reliability compared to the skill eating, the main reason being that drinking is a rather simple skill, which cannot be performed in many ways, whereas the skill eating consists of more sub movements and may be performed in many different ways. Between-subject reliability of the skill eating was relatively low, especially for the performance without instruction in the youngest children, the reason being that many children did not use the knife to cut the food, whereas other children had difficulties manipulating the knife. In the instruction condition, they were told how to use the knife. In conclusion, using multiple body worn sensors enable us to reliably record activities of daily life in healthy adults and children. Future research will focus on signal reliability during activities of daily life performed by *patients* and in *daily life settings*.

PO-0387

BIPLANE FLUOROSCOPE MEASUREMENT OF SCAPULOHUMERAL KINEMATICS IN HEALTHY AND POST-OPERATIVE POPULATIONS

Ashley Hannon [1,*]Tom Jenkyn [2]

[1]Kinesiology, [2]Engineering, Western University, London, Canada

Introduction and Objectives: Glenohumeral kinematics in both healthy and pathologic shoulders is essential for evaluation of current clinical practices. Quantifying the motion during abduction(ABD), flexion(FF), and compound motion using a biplanar fluoroscopic technique in subjects with healthy, normal shoulders and post-surgical intervention for supraspinatus muscle repair uses a very accurate technique to describe motion in 3D, gaining insight for clinicians.

Methods: Six healthy normal subjects were performed one trial of right arm abduction(ABD) to 90˚, forward flexion(FF) to 90˚ and the compound motion of moving the right hand to the left shoulder (AAC). These were done at a self-selected pace. Two subjects diagnosed with right supraspinatus tear underwent surgical intervention to reattach the muscle. Six weeks after the surgical intervention, subjects also were recorded performing right arm ABD to 90˚, FF to 90˚ and AAC. Biplanar fluoroscopy was collected at 30 Hz on all subjects and was matched with a generic shoulder model. A radiostereometric analysis technique was employed to obtain the angles of the humerus in relation to the scapula for the motions. Data was filtered with a 4th lowpass Butterworth filter with a cutoff frequenzy of 3Hz. Data was normalized to 100% of motion and ensembled by group. Standard error was calculated to determine excursion from the mean. Descriptive statistics were determined for all three rotations of the humerus in relation to scapula, translations measuring the movement of the centre of the humeral head in relation to the origin of the scapular coordinate system at the acromial angle.

Results: Excursion values for motion of ensembled data for plane of elevation, angle of elevation and internal/external rotation grew as the range of motion increased in all trials. ABD trials had more excursion than those of FF. Rotation values for ABD and FF were similar to the values previously reported [1]. The surgical intervention group stayed within, or close to the values for the healthy, normal subjects. Variance in plane of rotation and angle of rotation were greater in ABD and FF than AAC(fig1).

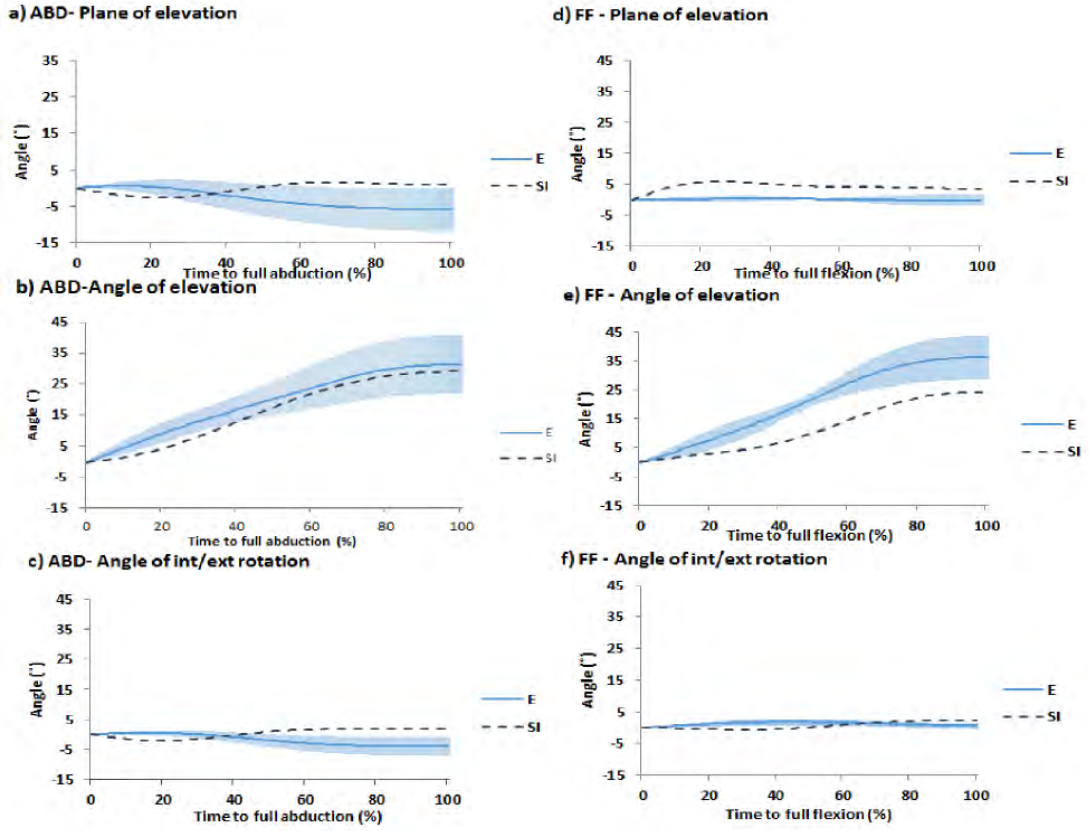
Subjects in the healthy group measured ABD rotations at 90 ˚ of -5.77˚ ± 11.96˚ for plane of rotation, 31.44˚ ± 19.09˚ for angle of rotation, and -3.81˚ ± 6.18˚ for axial rotation (external). For the surgical intervention ABD rotations at 90 ˚ were -11.97˚ ± 20.02˚ for plane of rotation, 29.20˚ ± 39.68˚ for angle of rotation, and -9.81˚ ± 3.42˚ for axial rotation (external). Translations at 90 ˚ abduction were 1.74mm ±3.86mm in the x direction, 4.71mm ± 2.96mm in the y direction, and -1.96mm ± 3.88mm in the z direction for the healthy group and 3.23mm ± 4.66mm in the x direction, -9.17mm ± 3.78mm in the y direction, -5.4mm ± 6.12mm in the z direction for the post-surgical intervention group.

The FF rotations at 90 ˚ were -0.17˚ ± 4.79˚ for plane of rotation, 36.19˚ ± 18.58˚ for angle of rotation, and 0.71 ˚ ± 1.97˚ for axial rotation (internal). For the surgical intervention FF rotations at 90 ˚ were 3.55˚ ± 0.25˚ for plane of rotation, 24.26˚ ± 6.36˚ for angle of rotation, and 2.40˚ ± 0.13˚ for axial rotation (internal). Translations at 90 ˚ FF were -1.18 mm ±3.34 mm in the x direction, 1.24mm ± 2.72mm in the y direction, and -1.15mm ± 2.61mm in the z direction for the healthy group

and 0.36mm ± 1.84mm in the x direction, 0.36mm ± 1.84m in the y direction, -1.85 mm ± 3.33 mm in the z direction for the post-surgical intervention group.

Full AAC measured 1.11˚ ±5.50˚ for plane of rotation, 30.09˚ ± 9.84˚ for angle of rotation, and 3.13˚ ± 9.60˚ for axial rotation (internal). For the surgical intervention, full AAC measured 7.41˚ ± 1.21˚ for plane of rotation, 14.65˚ ± 16.33˚ for angle of rotation, and 4.57˚ ± 3.17˚ for axial rotation (external). Translations at full AAC were -1.25mm ± 2.25mm in the x direction, 5.35mm ± 2.90mm in the y direction, and 3.32mm ± 2.61mm in the z direction for the healthy group and 4.96mm ± 0.59mm, 5.82 mm ± 3.63mm, -3.00mm ± 1.37mm for the post-surgical intervention group.

Figure:



Caption: Figure 1: Rotations for ABD and FF in healthy (E) and surgical intervention (SI) groups

Conclusion: Biplanar fluoroscopy continues to be considered the gold-standard for in-vivo motion quantification. The use of a generic shoulder reduced the amount of radiations subjects were exposed to, while maintaining a high accuracy. Large excursion values illustrate that scapulohumeral motion is quite complicated due to 6 degrees of freedom where various combinations of translations and rotations could facilitate the same response. Subtle differences exist between the group with healthy shoulders and the group with surgical intervention in abduction and significant differences were calculated between groups during FF. Some of these differences may be explained through physical compensation and increased muscular synergies in the post-surgical intervention group.

EVALUATION OF FINGER INTERDEPENDENCIES DURING ACTIVITIES OF DAILY LIVING

Victor Gonzalez [1 2,*] Jennifer Rowson [1 2] Alaster Yoxall [3]

[1]Department of Mechanical Engineering, [2]Insigneo Institute for in silico Medicine, The University of Sheffield, [3]Art and Design Research Centre, Sheffield Hallam University, Sheffield, United Kingdom

Introduction and Objectives: Dexterity assessment is important in the clinical medicine, inclusive design, and biomechanical fields. However, most movement assessment results require an understanding of biomechanics, mathematics and statistics limiting its applicability within clinical and design practice.

This article reports an experimental study that aimed to quantitatively analyse motion correlation patterns across the fingers, and examine the kinematic synergies during manipulative tasks, producing applicable and accessible data for therapy, product design, and research professionals.

Methods: Fifteen subjects performed 5 repetitions of two types of tasks: (1) activities of daily living and, (2) dexterity tests. The tasks were selected as representative of activities requiring the performance of the most commonly used grasping patterns (Table 1) [1][2]. A ten-camera opto-electronic system (Vicon, UK) measured trajectories of 26 reflective markers placed on selected hand dorsum landmarks (metacarpal base, MCP joints, proximal interphalangeal joints, distal interphalangeal joints and the nail).

Planar angular profiles for flexion–extension movements of the Metacarpophalangeal, Proximal Interphalangeal and Distal Interphalangeal joints, along with Thumb Abduction were derived from the measured markers' coordinates.

Cross-correlation coefficients were calculated for the joint angles corresponding to the selected movements for all tasks across all subjects and correlation matrices were derived from these values, representing finger movement interdependencies (Figure 1).

Results: Correlation matrices showed patterns of higher correlation (average 0.91, s.d. +/- 0.02) between joint angles for tasks requiring manipulation of small objects (Figure 1). Correlation patterns from dexterity tests confirmed this tendency across all subjects.

Higher correlation coefficients between motions were related with high proficiency in the dexterity tests for all subjects, even in those tasks requiring large object manipulations. Correlation matrices from the dexterity tests showed participants with the highest test scores had higher correlation coefficients among joint angles (Avg. 0.90, s.d. +/-0.03).

Subjects' movement correlation patterns suggest that, finger interdependency, required to proficiently complete a task, is related to the size of the object being manipulated. However, it is notable that in tasks requiring manipulation of larger objects, correlation values were lower, indicating that finger interdependencies are not necessary to accomplish all tasks proficiently.

There are convergences between new findings on kinematic synergies yielded from this study and some previous findings on hand coordination [3][4]. The current study shows a general trend of motion interdependence decreasing with anatomical distance and also a clear relationship between finger interdependency and performance of manipulative tasks. These findings are supported by what has been found from alternative methods of finger coordination quantification[3][5].

Figure:

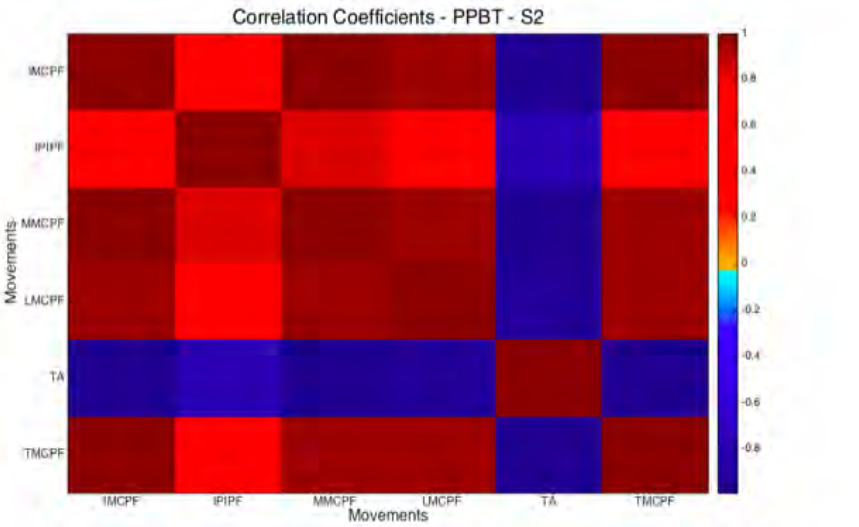

Figure 1. Correlation coefficients during completion of the Purdue Pegboard Dexterity Test for the measured movements: Index MCP Flexion (IMCPF), Index PIP Flexion (IPIPF), Middle MCP Flexion (MMCPF), Little finger MCP Flexion (LMCPF), Thumb Abduction (TA), and Thumb MCP Flexion (TMCPF)

Conclusion: The present study quantified finger interdependencies during several common manipulative tasks. Although such multi-joint acts could be carried out in seemingly an infinite number of ways, notable motion patterns do emerge as evidenced in this study. Correlation matrices allow for more applicable and accessible data, showing interdependencies patterns in a clear, observable representation. The study also rendered evidence to support the conjecture that while finger coordination is responsible for proficiency during manipulative tasks, finger interdependencies are not necessary for all types of tasks.

DEFINITION AND ASSESSMENT OF A MODIFIED CONSTANT SCORE THAT ACCOUNTS FOR ALTERATIONS IN SCAPULA KINEMATICS

Andrea Giovanni Cutti [1,*] Ilaria Parel [2] Andrea Pellegrini [3] Rinaldo Sacchetti [1] Paolo Paladini [4] Giuseppe Porcellini [4] Giovanni Merolla [4]

[1]Research & Development, Centro Protesi INAIL, Vigorso di Budrio, [2]"M. Simoncelli " Biomechanics Laboratory, Cervesi Hospital, Cattolica, [3]Clinica Ortopedica, Università di Parma, Parma, [4]Unit of Shoulder and Elbow Surgery, Cervesi Hospital, Cattolica, Italy

Introduction and Objectives: The Constant-Murley score (CMS) [1] is one of the most popular outcome measures for shoulder function [2,3]. It comprises 3 self-reported (pain and daily living) and 5 performance-based (shoulder mobility in elevation/rotation and strength) items, with score from 0 (worst) to 100 (best) points. During the assessment of mobility, only the humero-thoracic elevation is rated. Scapula kinematic alterations (dyskinesis) are not taken into account. This increases the risk of patients' suboptimal treatment, because an essential part of shoulder movement is neglected.
The first aim of this study was to propose a modification of CMS to account for alterations in the scapulo-humeral coordination (SHC). The new score was named Scapula-Weighted CMS (SW-CMS). The second aim was to evaluate the impact of these modifications on the scores of a group of patients after rotator cuff surgery. The ultimate goal is to understand how many patients are recovering a SHC similar to the one of the contralateral side and plan corrections in the rehabilitation approach, if needed.

Methods: We propose to weight the points for the humerus-thoracic elevation, based on the "affected-to-contralateral side difference in SHC" being greater than the typical difference in asymptomatic controls. The weighting factors W_{FE} and W_{AA} range between 0 and 1, and multiply the scores for humerus elevation in the sagittal and frontal plane, respectively (max 20 points). For a given patient, the value of W_{FE} and W_{AA} depends on the comparison of the side-to-side differences in SHC, with reference bands of asymptomatic subjects. For the motion analysis protocol ISEO [4], this set of reference prediction bands is available, separately for each scapula angle, i.e. protraction-retraction (PR-RE), medio-lateral rotation (ME-LA) and posterior-anterior tilting (P-A) [5]. In details, W_{FE} is calculated using the following rule; if the side-to-side difference during forward flexion is within the band for:

1) PR-RE vs FL-EX: $W_{FE\_PRRE}=0.3$
2) ME-LA vs FLEX: $W_{FE\_MELA}=0.3$
3) P-A vs FLEX: $W_{FE\_PA}=0.3$
4) if A, B, C are true then, $W_{FE\_BONUS}=0.1$

$W_{FE}=W_{FE\_PRRE}+W_{FE\_MELA}+W_{FE\_PA}+W_{FE\_BONUS}$

Similarly for W_{AA}, considering the elevation in the frontal plane.
The normalization of the CMS score of one side with the score of the contralateral increases the sensitivity and specificity [6]. This normalization was thus assumed for CMS and SW-CMS.

CMS and SW-CMS were applied on 32 patients (53±9 year-old, 15 males) surgically treated for rotator-cuff tear, after giving the informed consent. Each patient was assessed by a single rater at 45, 70, 90 days and > 6 months post-surgery (follow-up). Two hypotheses were then tested:

H1) CMS does not implicitly account for scapula-thoracic alterations: at each time, CMS and SW-CWS scores are significantly different;

H2) when SHC alterations are taken into account as in SW-CMS, the patients assigned a "good score" (>80 – [7]) decreases, but the "successful" patients are the 90% at 90 days.

To answer to H1 a linear mixed model with repeated measures was run in SPSS 17. The repeated measures were the *Scoring* system (fixed; CMS, SW-CMS) and the *Time* (fixed+random; 45, 70, 90, >6 months). Pairwise comparisons were calculated within *Time*, *Scoring* and their interactions. To answer to H2, at each *Time* we calculated the number of patients with a score >80 points for CMS and SW-CMS.

Results: Differences in *Scoring*, *Time*, and their interaction were statistically significant ($p < 0.40$). At each *Time*, CMS and SW-CMS were statistically different ($p<0.000$), with differences increasing from 6.5 to 10.25 points, at 45 days and follow-up, respectively. This supports the validity of H1.

Figure 1 reports the number of patients with scores >80 for CMS and SW-CMS at each time point. While both scores agree at 45 days, the difference in classification reaches a peak of 70% at 90 days: while for CMS 10/32 patients featured a "good" recovery, for SW-CMS only 3/32 exceeded 80 points. This indicates that H2 is unsupported.

Figure:

Time	CMS (absolute and %)	SW-CMS (absolute and %)	(CMS – SW-CMS)/CMS (%)
45	0 (0%)	0 (0%)	0%
70	4 (19%)	2 (9,5%)	50%
90	10 (31%)	3 (9,5%)	70%
Follow-up	28 (87,5%)	16 (50%)	43%

Caption: Figure 1. The number of patients with CMS and SW-CMS scores > 80 points.

Conclusion: Based on the results, CMS does not implicitly account for the SHC alterations. Moreover, results for H2 point out that the recovery of SHC is challenging and a minority of patients achieve this goal, especially at 90 days post-op. Therefore, improved rehabilitation programs for scapula-control should be implemented, e.g. through biofeedback.

PRINCIPAL COMPONENT ANALYSIS APPLICATION ON SCAPULOTHORACIC KINEMATIC IN HEALTHY AND SHOULDER PAIN SUBJECTS

Denise M. Rossi [1,*] Renan Resende [2] Sérgio Fonseca [3] Anamaria Oliveira [1]

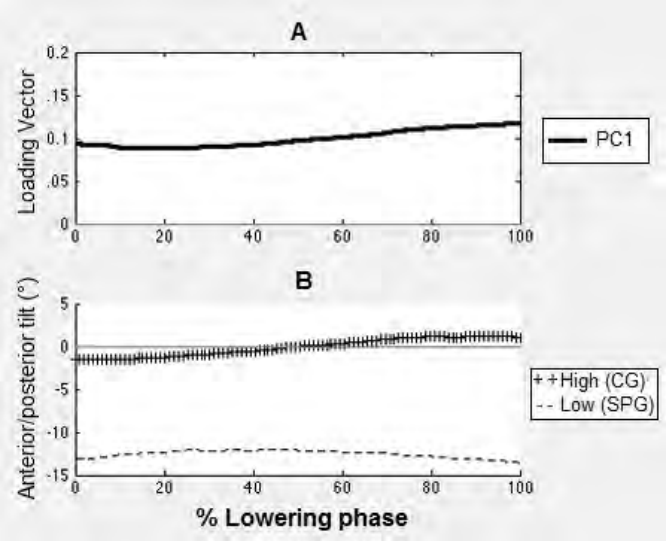
[1]Department of Biomechanics, Medicine and Rehabilitation of Locomotive Apparatus, Ribeirao Preto Medical School - University of São Paulo, Ribeirão Preto, [2]Department of Physiotherapy, Faculty of Biological Sciences and Health, Universidade Federal dos Vales do Jequitinhonha e Mucuri, Diamantina, [3]Department of Physiotherapy, School of Physical Education, Physiotherapy and Occupational Therapy, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Introduction and Objectives: Appropriate scapular position and movement is fundamental to maintenance of stress and forces transmission mechanism and this knowledge is important to evaluation and intervention of shoulder clinical conditions [1,2]. There is evidence of scapular involvement in several types of shoulder pathology, but there is limited understanding of scapula role in creating or exacerbating shoulder disorders [3]. Furthermore, kinematic alterations are also present in asymptomatic persons [4]. Physical therapists are specialized in management of movement related disorders and are able to differ non-desirable movement from typical movement and kinematics methods make these observations measurable and quantifiable [5]. Variability is an inherent feature of human movement and it can provide notable information concerning the neuromuscular system function [6]. Principal Component Analysis (PCA) is a decomposition technique used to identify patterns of variation in the waveform data that are independent of each other, thus allowing comparisons of different features of the data. Although PCA has been extensively used in biomechanics, it has not been frequently applied to shoulder complex [6]. Therefore, the purpose of this study was to apply PCA on scapulothoracic kinematics data of healthy and shoulder pain subjects in order to investigate differences between groups.
Methods: This study demonstrates preliminary data of 11 participants divided into two groups. Shoulder pain group (SPG) included five participants with shoulder pain and the control group (CG) had six participants without shoulder pain. Symptomatic group included subjects with painful arc and positive impingement tests (Hawkins-Kennedy and Neer). Three-dimensional position and orientation of each subject's thorax, scapular and humerus were tracked (120 Hz sampling rate) using electromagnetic Liberty ® (Polhemus Inc) system according to ISB international recommendations. After fixing sensors and digitization of landmarks in anatomical segments, data were collected during the arm elevation and lowering in the sagittal plane. Analyses were performed in dominant member in CG and member painful in SPG. Ten complete elevation-lowering cycles were collected, but only one of the three last was considered for PCA analysis. The analysis of scapular movements relative to the thorax was made using Euler angle rotation sequence of YX'Z'' and for the humeral movements relative to the thorax was used XZ'Y''. The PCA was applied to determine the main features of the scapulothoracic kinematics in the waveform data. PCA generates principal components, which represent the patterns of variation in the original data. In addition, PCA generates scores for each original waveform on each principal component (PC), and these scores are used as dependent variables for comparisons between groups. The PCA analysis was performed to each scapular movement, inernal/external rotation, upward/downward rotation and anterior/posterior tilt,

during the arm elevation and lowering, separately. A criteria of 90% of variance explained was used to determine the number of principal components to retain for data analysis The movement cycle was normalized in 100 points between 20° and 120° of humerothoracic elevation. Student's t-Test for Independent Samples was performed to comparison between groups with α set at 0.05.

Results: The SPG group demonstrated increased scapular anterior tilt during the lowering phase when compared to the CG group (p = 0.05). The first PC captured 88.13% of the total variance observed in scapular tilt over time and across participants. The PC2 captured 10.52% of the total variance, but only the score of PC1 differed between groups, being lower for the SPG. Figure 1A shows that the PC1 loading vector contains coefficients of large magnitudes corresponding to scapular tilt values during the entire lowering phase. The reconstructed waveforms displayed in Figure 1B suggest that lower mean score of the SPG reflects lower magnitude of posterior tilt, i.e. increased scapular anterior tilt.

Figure:



Caption: Figure 1. (A) The loading vector for PC1. (B) Scapular anterior/posterior tilt corresponding to high and low PC1 scores demonstrate the difference in magnitude during the entire lowering phase. Higher scores for control group (CG) and lower scores for shoulder pain group (SPG). Negative number indicates anterior tilt.

Conclusion: There is difference evidence in scapulothoracic kinematics waveform data between healthy and shoulder pain subjects. Despite small sample, pain seems to influence the variability pattern in order to increase scapular anterior tilt during the arm lowering.

INFLUENCE OF HUMERAL POSITION AND EXTERNAL LOAD ON ELECTROMYOGRAPHICAL ACTIVITY OF TRAPEZIUS AND SERRATUS ANTERIOR MUSCLES DURING EXTERNAL SHOULDER ROTATION

Vilma Juodzbaliene [1,*] Giedre Jurgelaitiene [1] Rolandas Kesminas [1] Giedre Valiukaite [1]

[1] Applied Biology and Rehabilitation, Lithuanian Sports University, Kaunas, Lithuania

Introduction and Objectives: The position and movements of scapula is essential for appropriate humeral head position and for stable base to support motions of the shoulder in daily life and sport activities. Trapezius and serratus anterior is the most important muscles to stabilize scapula during upper extremity movements [1, 2]. Scapula dyskinesis occur 68 – 100% of shoulder injuries [3]. In a many studies scapula dyskinesis was found in patients with shoulder impingement syndrome, rotator cuff tendinopathy and tears, adhesive capsulitis, shoulder instability [4, 5, 6]. The aim of shoulder injuries rehabilitation – restore the position of scapula and movements in scapulothoracic joint. Conservative treatment consist of scapula stabilizers strengthening, therefore it is important to choose the right exercise on shoulder rehabilitation protocol [7]. External shoulder rotation at 90°of humeral abduction was suggested for scapula stabilizers strengthening [8]. It is important to know influence of different humeral position and different external load during external shoulder rotation [8]. **Goal of the study**: Evaluate influence of humeral position and external load on electromyographical activity of trapezius and serratus anterior muscles during external shoulder rotation.

Objectives of the study:

1. Evaluate electromyographical activity of upper, middle and lower parts of the trapezius and serratus anterior muscles.
2. Evaluate electromyographical activity of upper, middle and lower parts of the trapezius and serratus anterior muscles.
3. Compare electromyographical activity between upper, middle and lower parts of the trapezius and serratus muscles.

Methods: Subjects: 18 highly physically active (according IPAQ) non professional athletes took part in the study (age 20-25 years, dominant hand - right).

Criteria of subject inclusion: there is no pain in the shoulder region, have no previous shoulder injuries or surgery, full ROM, have no systemic diseases, no scapular dyskinesis, normal BMI and correct posture.

Methods: Electromyographical activity of upper, middle and lower trapezius as well as serratus anterior was registered using surface electrodes during external shoulder rotation at 0°, 45° and 90° of shoulder abduction and with different external load.

Results: External shoulder rotation produced highest electrical activity of trapezius and serratus anterior muscles at 90° of shoulder abduction and lowest at 0° of shoulder abduction ($p<0,05$). Electromyographical activity of trapezius and serratus anterior muscles was higher increasing the load on external shoulder rotation ($p<0,05$). Lower trapezius was the most active during external shoulder rotation at all shoulder loading positions. Upper trapezius and serratus anterior was least active at 0° of shoulder abduction ($p<0,05$).

Conclusion: Electromyographical activity of trapezius and serratus anterior muscles increase with greater external load and shoulder abduction from 0 to 90°.

PO-0392

CAN WE NEGLECT AGE-SPECIFIC DIFFERENCES IN THE SCAPULO-HUMERAL COORDINATION WHEN EXAMINING A PATIENT?

Ilaria Parel [1 2,*] Rinaldo Sacchetti [1] Giovanni Merolla [2] Giuseppe Porcellini [2] Andrea Giovanni Cutti [1]

[1]INAIL Centro Protesi, INAIL, Vigorso di Budrio, [2]Laboratory of Biomechanics, Cervesi Hospital - AUSL della Romagna, Cattolica, Italy

Introduction and Objectives: The assessment of scapulo-thoracic motion in relation to humerus elevation, i.e. the "scapulo-humeral coordination" (SHC), plays a central role in the clinical management of patients with shoulder disorders [1]. SHC is typically evaluated by means of coordination plots, where SHC is described as a curve that correlates scapula angles variation to humerus elevation. To date, several quantitative motion analysis protocols have been developed to support in the examination of the multi-planar SHC, but, in order to use them in the clinical practice, reference values are essential. To answer this need, for the ISEO protocol [2] a set of reference prediction bands (RPB) was calculated [3], and, to date, ISEO is the only protocol that provides reference data for clinical assessment. These data were calculated separately for each scapula angle, i.e. protraction-retraction (PR-RE), medio-lateral rotation (ME-LA) and posterior-anterior tilting (P-A), during humerus elevation. RPB were computed for three age-stratified groups and differences in shape of RPB were described qualitatively. The aim of this study is to quantify the probability of misclassification when the kinematics of a patient is compared to RPB based on data of a not correspondent age-group.

Methods: One hundred eleven asymptomatic subjects (mean age ± SD: 38 ± 14) were recruited for this study after giving their informed consent. The subjects were split in 3 groups, depending on the age:

- G1, from 18 to 30 year-old, 46 subjects;
- G2, from 31 to 50 year-old, 35 subjects;
- G3, from 51 to 70 year-old 30 subjects.

The 90% coverage probability RB for humerus elevation both in the sagittal (FL-EX) and scapular (AB-AD) plane reported by Cutti et al [3] were considered. To assess the risk of misclassification of reference data from G1, a cross-comparison analysis was conducted. Kinematic data of subjects from G2 and G3 were compared to RB from G1 and cover-indexes (CI) calculated:

- CI = (total n° of subjects – n° subjects out of the band/interval) / total n° of subjects

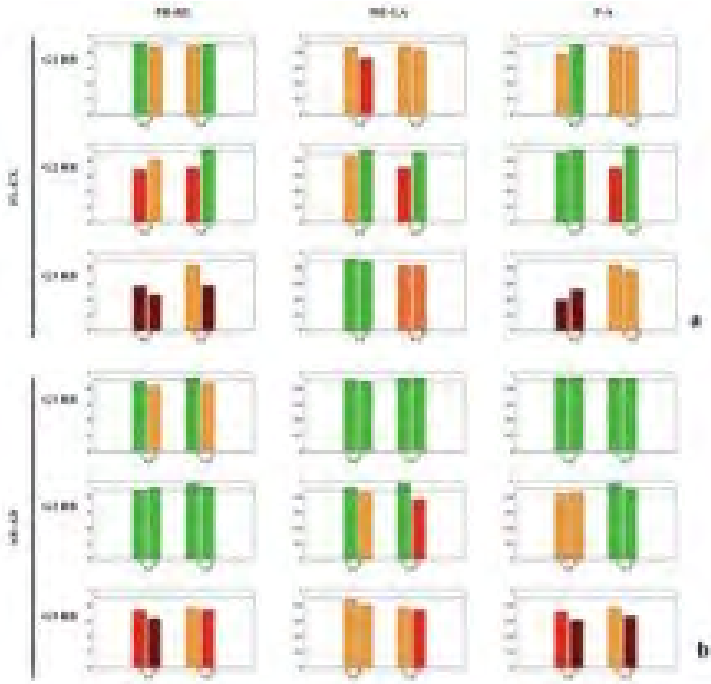
Considering 0.87 as the minimum coverage probability resulting from comparison of group data with correspondent RB (e.g. kinematic data of subjects from G1 compared to G1-RB), the coverage probability was classified as good when CI ≥ 0.87, moderate when 0.87 > CI ≥ 0.77, poor when 0.77 > CI ≥ 0.67 and very poor when CI < 0.67. The same cross-comparison analysis was conducted also for G2 and G3.

Results: Results are summarized in Figure 1. Risk of misclassification is increased as follows:

- < 10%, green bars, for 29/72 (40%) bands (11 in FL-EX, 18 in AB-AD);
- 10%, orange bars, for 25/72 (35%) bands (15 in FL-EX, 10 in AB-AD);
- 20%, red bars, for 10/72 (14%) bands (5 in FL-EX, 5 in AB-AD);

- 30% or more, brown bars, for 7/72 (10%) bands (4 in FL-EX, 3 in AB-AD).

Figure:



Caption: Results from cross-comparison analysis for RPB in FL-EX and AB-AD. Each row reports comparisons with respect to G1, G2 and G3 for RPB in FL-EX (a) and AB-AD (b). Each column reports results for the three scapula angles: PR-RE, ME-LA and P-A. Within each subplot, CIs from the comparison of upward (U) and downward (D) RPB with respect to “other” groups are reported. Color classification: green CI ≥ 0.87; orange 0.87 > CI ≥ 0.77; red 0.77 > CI ≥ 0.67; brown CI < 0.67.

Conclusion: Results from the analysis of the coverage probability in cross-comparison analyses highlighted that the specificity of each group should be taken into account: a general decrease of the classification-power occurs when the kinematics of a subject is compared to reference data obtained from subject belonging to other age-group. Orange, red and brown bars indicate that excessive sensitivity of the RPB can increase the risk of false-positive results, i.e. a sound kinematics is classified as altered. Otherwise, if a minimization of the risk of false-positive is sought, G1 RPB can be used to classify G2 and G3, lowering the specificity of the analysis, and increasing the risk of false-negative, i.e. an altered kinematics is classified as sound.

PO-0393

CORRELATION OF 3-D SCAPULAR KINEMATICS TO FUNCTION IN SUBJECTS WITH CHRONIC STROKE

Maíra Lixandrão [1,*] Paula Camargo [1] Christiane Prado-Medeiros [1] Tania Salvini [1]

[1] Departament of Physical Therapy, Universidade Federal de São Carlos, São Carlos, Brazil

Introduction and Objectives: Motor impairments following stroke may lead to scapular abnormal movements and thus can limit upper limb function. Position and control of the scapula on the thorax play a critical role in normal function of the shoulder. Scapular motions on the thorax align the glenoid fossa with the humeral head maximizing joint congruency and providing a stable base for humeral motion (Phadke et al., 2009). Therefore, an adequate scapular function can be critical for place the hand through a wide range of motion in space during activities of daily living. However, it is not known yet if there is a correlation between scapular kinematics and upper limb functionality after chronic stroke.

Methods: Fifteen individuals with chronic stroke (11 male and 4 female; 11 with dominant arm as more-affected arm; 58.14 ± 7.89 years; 24.49 ± 3.27 Kg/m²) were included in the study. Upper limb functionality was evaluated using Motor Activity Log (MAL). This instrument is a structured interview intended to examine how much and how well the subject uses their more-affected arm to accomplish 30 activities of daily living outside of the laboratory setting. The MAL is composed of quantitative and qualitative scales. Both of them are scored on six points, ranging from zero (never used) to five (the same as pre-stroke), and participants may select halfway scores. In each scale a total score corresponds to the mean of the items, calculated by the sum of the scores of all items, divided by the number of the accomplished items responded (minimum score = 0 and maximum score = 5 points). Kinematic data were collected using the Flock of Birds® electromagnetic tracking system during elevation and lowering of the more-affected arm in the scapular plane. Local coordinate systems were established for the trunk, scapula, and humerus using the digitized landmarks, following the International Society of Biomechanics recommended protocol (Wu et al., 2005). Five repetitions of the activity were recorded with subjects in the sitting position and trunk stabilized. Data analysis for scapular orientation was performed for selected angles of humerothoracic elevation (30°, 60° and 90°) and lowering (90°, 60° and 30°). Data were analyzed with the SPSS statistical package. Kolmogorov-Smirnov tests were used to check data normality. Once data do not present normal distribution a Spearman correlation test was used to identify correlations between scapular motion and MAL scores. The level of significance was considered 5%.

Results: A moderate correlation was found between MAL quantitative scale and scapular internal rotation during lowering of the arm at 60º ($r = 0.68$, $p = 0.005$) and 30º ($r = 0.60$, $p = 0.01$). MAL quantitative scale also correlated with scapular tilt during lowering of the arm at 90º ($r = 0.63$, $p = 0.01$). A moderate correlation was observed between MAL qualitative scale and scapular internal rotation during lowering of the arm at 90º ($r = 0.61$, $p = 0.01$), 60º ($r = 0.62$, $p = 0.01$) and 30º ($r = 0.59$, $p = 0.02$). A high correlation was found between MAL quantitative scale and scapular internal rotation during lowering of the arm at 90º ($r = 0.72$, $p = 0.002$) and between MAL qualitative scale and scapular tilt during lowering of the arm at 90º ($r = 0.72$, $p = 0.02$). There was no correlation between scapular upper rotation and MAL scores ($p > 0.05$). Scapular movements are necessary to accomplish activities like feeding, combing hair, reaching overhead and washing the

contralateral axilla (Rundquist et al., 2011). Our results showed that scapular specific movements are related to general functionality of more-affected arm in stroke patients. Scapular internal rotation during lowering of the more-affected arm at high angles seems to be more related to quantity of upper arm movements whereas scapular tilt seems to be more related to quality of upper arm movements in stroke patients.

Conclusion: More-affected upper limb functionality is correlated to scapular internal rotation and scapular tilt during lowering of the arm in scapular plane in chronic stroke subjects. Interventions addressing these scapular movements in chronic stroke patients may improve performance of activities of daily living.

IN VIVO CONTACT STRESS EVALUATION IN THE TRAPEZIOMETACARPAL JOINT USING FINITE DEFORMATION BIPHASIC THEORY AND MATHEMATICAL MODELING

Benjamin Dourthe [1,*] Priscilla D'Agostino [1] Filip Stockmans [1 2] Faes Kerkhof [1] Evie Vereecke [1]

[1]Development and Regeneration, KU Leuven, [2]AZ Groeninge, Kortrijk, Belgium

Introduction and Objectives: Osteoarthritis (OA) is a degenerative joint disease characterized by the loss of articular cartilage and remains a complex, disabling disease which cause is not completely understood.

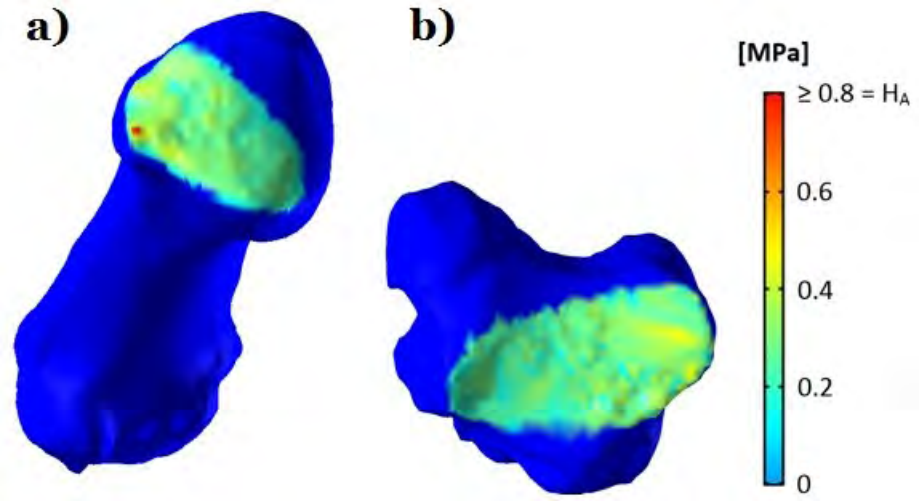
Evaluating the stress distribution within the trapeziometacarpal (TMC) joint during daily activities is a clinically relevant way to investigate the biomechanical behavior of this complex articular system. Such insights will also lead to a better understanding of joint functioning and can help predict which part of the joint will be primarily affected by degenerative changes in the onset of OA. This is particularly important in establishing new prevention approaches.

The main objectives of this study are: (1) to evaluate the amount of stress occurring around the first metacarpal (MC1) and the trapezium bone during different isometric tasks, and (2) to identify which specific articular region undergoes the highest level of stress according to various loaded positions.

Methods: After permission by the medical ethical commission of the University, CT scans were obtained from 20 female volunteers (mean age: 60.8 years) using a 64 slice Discovery HD 750 CT scanner (GE Healthcare) in AZ Groeninge, Belgium. Static CT scans (slice thickness: 0.625mm, pixel size: 0.391 mm) of the hand region were taken in three different configurations: relaxed neutral, lateral key pinch and power grasp, using a radiolucent jig with embedded load cell (Brown University, USA). The applied force was recorded during a submaximal effort (80% of maximal strength) during each task. Each scan was segmented and 3D bone models were created using Mimics v. Research 17.0 x 64 (Materialise, Belgium). Four subjects showing signs of OA were excluded from the study. The total articular area of each bone was evaluated manually using 3-matic v. Research 9.0 x 64 (Materialise, Belgium). A custom-written MatLab code - based on the finite deformation biphasic theory[1] and cartilage deformation properties taken from the literature[1], [2] - was used to evaluate the contact area for each bone, as well as the contact stress distribution. The location of the most stressed area was evaluated using a quadrant division as defined by Momose et al (1999)[3].

Results: We observed no significant difference between the total articular area of MC1 and the trapezium of each subject. The trapezium, however, had a slightly smaller contact area compared to MC1. This difference was only statistically significant in the lateral pinch position ($p<0.05$; neutral: $p=0.05$; grasp: $p=0.07$). The contact stress calculation revealed a similar maximal contact stress value between the neutral position and the lateral key pinch task, while this parameter was increased during the power grasp. Similar results were found by studying the average stress distribution across the joint. We observed a stress concentration around the volar beak of MC1 and the volar-ulnar aspect of the trapezium in the neutral position, as well as in the lateral key pinch position, with a few subjects showing a stress concentration around the radial aspect of the trapezium. The ulnar aspect of both MC1 and the trapezium was shown as the most constrained during power grasp with a strong consistency between subjects.

Figure:



Caption: Stress distribution in the TMC joint of one subject during power grasp - a) MC1 - b) Trapezium (right hand)

Conclusion: These results suggest that for a similar load, the contact area of the trapezium appears to be smaller than for the first metacarpal, at least in the pinch position. This could show a larger stress concentration on specific aspects of the trapezium, which we assume to indicate that the trapezium is the first bone of the TMC joint to be affected by degenerative changes. However, a larger sample size is needed to further investigate this with a higher statistical power. Such insights could be of high interest in predicting which component of the TMC joint will be primarily affected by degenerative changes. Moreover, we observed a higher average stress value in the power grasp configuration compared to the neutral position and the lateral pinch task. This could highlight two interesting findings: (1) lateral key pinch does not represent a critical task to evaluate stressful configurations in the TMC joint, (2) performing a power grasp can elicit higher amounts of stress in the TMC joint, which is of interest when studying joint stability. Furthermore, the consistency of the results regarding the stress location for the different positions provides a relevant way of understanding the biomechanics of this complex joint. This study shows the importance of performing in vivo assessments of the mechanical behavior of the TMC joint by using advanced modelling techniques to provide a better understanding of this articular system in the early onset of osteoarthritis.

COMSOL ANALYSIS OF WHEELCHAIR PUSHRIM SIX DOF LOAD CELL FOR QUANTIFYING PROPULSION EFFICIENCY BY SENSEWHEEL

Tatsuto Suzuki [1,*] Catherine Holloway [1] Andrew Symonds [2] Peter Smitham [3] Stephen Taylor [2]

[1]Civil, Environmental & Geomatic Engineering, [2]Biomedical Engineering, [3]Orthopaedic Surgery, University College London, London, United Kingdom

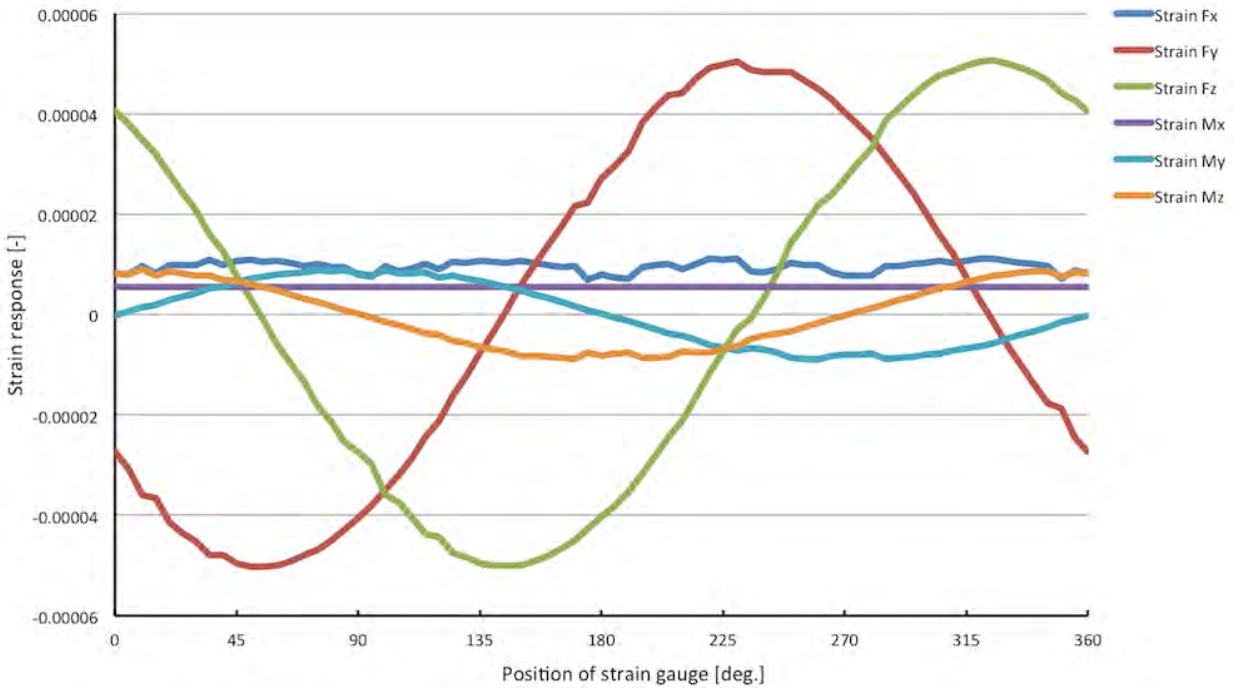
Introduction and Objectives: Manual wheelchair users rely on their upper extremities for self-propulsion of their wheelchair. This, over time, causes many users to suffer shoulder pain and injury, due to unconscious overuse [1]. Training in cost-efficient pushing style has the potential to alleviate pain, with resulting NHS savings. This can be assessed by measuring the 3D force acting at the pushrim.

The SenseWheel is a lightweight force-sensing handrim, comprised of three identical load cells. The load cells are interposed between the pushrim and drive wheel. The initial design SenseWheel Mk 1 measured the three orthogonal forces Fx, Fy and Fz, and axial torque Tx, applied at each load cell [2]. It has been constructed, calibrated, and used in a limited clinical trial. SenseWheel Mk1 is: 1) light weight (less than 100g), 2) able to fit s different diameter wheel or hand rim and 3) Waterproof. This paper describes the development of an improved Mk2 version of Sensewheel which uses wireless 6DOF load cells to measure Fx, Fy, Fz, Tx, Ty, and Tz. This will simplify the coupling to the wheel and handrim. Each load cell will transmit its data via Bluetooth to a master tablet/SmartPhone carried by the user or held remotely.

Methods: COMSOL was used to redesign the 6DOF load cell, using 8 quarter-bridge strain gauges equi-spaced around the inner circumference of the widest part of the load cell for good strain sensitivity and selectivity. This provided some redundancy in case of non-optimal gauge placement in the actual load cell. Each load cell is 40mm diameter at its widest, to accommodate coin cell, Bluetooth module and flexible printed circuit. The optimum orientation of the gauges was determined using COMSOL Multiphysics® with a 3D axis-symmetric finite element model generated from a 2D cross sectional model. The load cell was designed as two halves, to be screwed together after assembly, and this was modelled in COMSOL as one part. COMSOL was set to output direct strains (eX, eY, and eZ) as well as shear strains (eXY, eYZ, and eZX) in response to applied forces Fx, Fy, Fz, and torques Tx, Ty, and Tz. The strains were calculated at 5 deg intervals along the circumference of the inside wall of the load cell. These strains were then converted from the global axis of the model to the local axis at each strain gauge site using a rotation transformation matrix. The resulting strains were used to investigate both the sensitivity of each gauge to each load type, and also the selectivity of each load type. The gauge angle w.r.t. the longitudinal axis of the load cell was varied, and the strain sensitivities logged. The gauges of one semicircle of gauges were angled opposite the other semicircle to allow for separation between Fx and Mx, as previously used in an instrumented shoulder implant [3]. The correlation coefficient between force/moment pairs was then calculated to predict the optimum angle, which would give best separation between these load types. Importantly, this analysis demonstrated that the strain response, of 8 strain gauges at 45deg intervals around the circumference, to each applied load direction. is clearly distinguishable from the other load types.

Results: The peak sensitivity of the strain output by radial position, for several strain gauge angles w.r.t. the longitudinal axis, and the correlation coefficient between same axis force/moment pairs, is shown in Table 1. Figure 1 shows the strains at 5 deg increments around the circumference, for a gauge angle of 45deg, which gave a compromise between good strain sensitivity to each applied load, and adequate selectivity between load types. The designed load cells will now be manufactured, and following assembly each load cell will be calibrated to relate each strain output to each load type applied via a cross-sensitivity matrix, and measured loads are then combined to find the resultant force system on the pushrim.

Figure:



Caption: Figure 1 Strain response around circumference for six load types (DOF) (The angle of strain gauge is 45deg.)

Conclusion: The optimum angle for all gauges was found to be about 45 deg with respect to the longitudinal direction. This provided good sensitivity and separation of force components. Based on this COMSOL analysis, a wireless version of the SenseWheel will be developed, on a mobile platform. A musculoskeletal model is being developed to infer the shoulder forces, to be animated by these pushrim forces.

THE PROPER SEAT POSITION OF THE STANDING WHEELCHAIR

Jeseong Ryu [1,*] Isu Shin [1] Baekdong Cha [1] Jongman Kim [1] Soonjae Ahn [1] Jongsang Son [1] Youngho Kim [1]

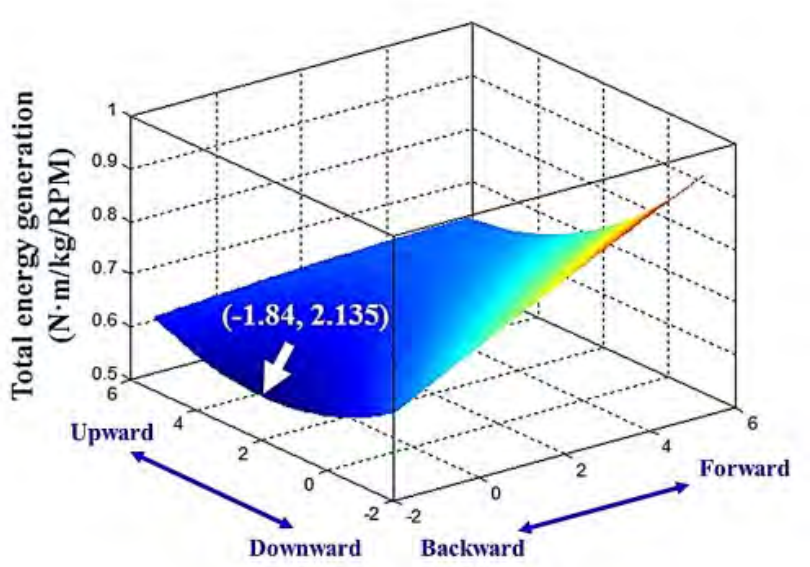
[1] Biomedical Engineering, Yonsei University, Wonju, Korea, Republic Of

Introduction and Objectives: Approximately 73% of manual wheelchair users suffer from pain and injury on their upper extremities [1]. The shoulder pain and injury are the most common for manual wheelchair users. To prevent upper extremity injury, many studies have been performed for the correct seat position and effective propulsion motion. Engel et al. [2] compared three different seat positions and showed posterior seat position was the most efficient place. Van der Woude et al. [3] studied the effect of seat height on energy consumption and kinematics, and recommended the optimal elbow joint angle and seat position. Recently, in order to increase convenience for wheelchair users, a specially-designed standing wheelchair to move even in a standing posture have been developed. Since this wheelchair has separated hand rim from the wheel, an optimal design of the seat position is required.

Methods: In this study, 5 healthy male subjects (23.8±1.8 years, 71.6±5.5kg, 172.8±7.2cm) were participated (approved by the Institutional Review Board of Yonsei University (No. 1041849-201406-BM-029-01)). A prototype of the manual standing wheelchair (HANIL Hightech Co., LTD, Republic of Korea) was fixed on a brake-type wheelchair dynamometer for the measurement of torque and rotation [4]. The brake torque was set to 3 Volt (axis retarding torque 0.55Nm), and torque and RPM were sampled at 1 kHz. Nine spherical reflective markers of 6.4 mm diameter were attached on the right upper limb according to the Plug-In-Gait (PIG) model (Oxford Metrics) and a wheelchair hand rim [5], and motion kinematics was obtained at 200 Hz using the 3D motion capture system (Vicon MX system, Vicon Motion System Ltd, UK). The seat and the back supporter were moved ±6cm in both horizontal and vertical directions from the center position, thus nine different positions were tested for every subject. The subject propelled 6 times in each position at his self-selected speed, and the selection of the seat position was randomly chosen. Upper-limb joint moments and total propulsion energy were determined using the inverse dynamics and the optimization based on the minimal joint power criterion with a link-segment model [6].

Results: We assumed that the optimal seat position has the lowest total energy. As a result, a short subject showed the smallest total propulsion energy on the highest seat position, whereas tall subjects showed the largest total propulsion energy on the lowest seat position. Regardless of the subject's height, the backward seat position, however, showed the smallest total propulsion energy in the horizontal position (Table). Figure shows the optimal seat position for all subjects, using the surface fitting. As a result, the smallest total energy was shown at 1.84% backward and 2.14% upward position in proportion to the subject height from the center position.

Figure:



Caption: Surface fitting of the optimal seat position for all subjects

Conclusion: In this study, biomechanical analysis was performed to determine an optimal seat position for a standing wheelchair which has the separated hand rim from the wheel. Kotajarvi et al. [7] examined the effect of seat position on the hand rim biomechanics using the typical wheelchair. They measured the effective force during propulsion with the changed seat position. Results showed that tangential force output did not change with the seat position, and axial and radial forces were largest in the lowest seat position. Therefore, they concluded that the propulsion efficiency did not significantly change with the seat position. In the study, joint moments and total propulsion energy were determined with the inverse dynamics and the optimization technique. A short subject showed the smallest total propulsion energy on the highest seat position, whereas tall subjects showed the largest total propulsion energy on the lowest seat position. Total propulsion energy of all subjects was the smallest on 1.84% backward and 2.16% upward from a center seat position proportional to the height. Further study is needed to compare young people and the elderly to develop a standing wheelchair with the optimal seat position.

SUPERCRITICAL CARBON DIOXIDE DECELLULARISATION OF PERICARDIUM: MECHANICAL AND STRUCTURAL CHARACTERISATION FOR APPLICATIONS IN CARDIOVASCULAR SURGERY

Frank R. Halfwerk [1 2,*] Jeroen Rouwkema [1] Jan Gossen [3] Bart Koopman [1] Jan Grandjean [1 2]

[1]Biomechanical Engineering, MIRA Institute for Biomedical Technology and Technical Medicine, University of Twente, [2]Thoraxcentrum Twente, Medisch Spectrum Twente Hospital, Enschede, [3]European Medical Contract Manufacturing, Nijmegen, Netherlands

Introduction and Objectives: Pericardium is used in cardiovascular surgery as a temporary graft for heart tissue recovery, reconstruction of heart valves and aortic wall, closure of pericardium and reconstruction of blood vessels (arterioplasty). However, calcification, dehiscence and formation of scar tissue occurs in the long term. These issues, in part, may be caused by decellularisation and cross-linking by glutaraldehyde, used to prevent a pro-inflammatory immune response. Current decellularisation methods are enzymatic, physical or chemical processes and result in disruption of architecture, reduction of mechanical properties and loss of surface composition. Importantly, residual chemicals inhibit beneficial properties of a cell-free scaffold.

Moreover, these treatments induce a chronic inflammation, which result in calcification and limit lifespan of the graft to 10 years. This calcification is related to host metabolism, implant structure and mechanical factors. Reoperation is often required, with high mortality, morbidities and costs.

A new method of decellularisation is supercritical carbon dioxide ($scCO_2$) processing; a mild but effective technique to remove cells and fat from tissues. This technique uses non-toxic chemicals and does not require cross-linking that interfere with degradation and a constructive remodelling process.

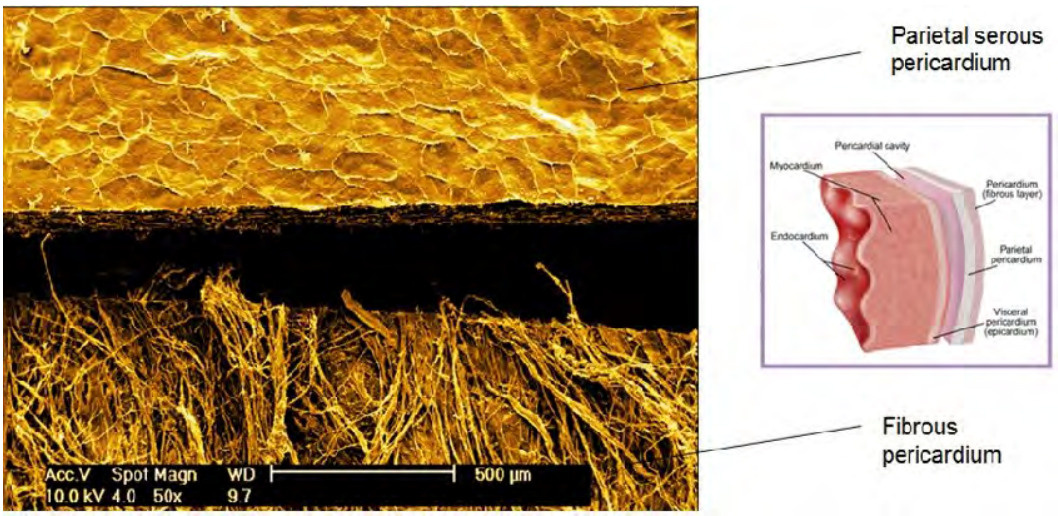
Thus, the aim of this study is characterisation of mechanical and structural properties of scCO2 decellularised pericardium for applications in cardiovascular surgery.

Methods: Bovine and porcine pericardia were decellularised by $scCO_2$ and compared with Peri-Guard® (bovine pericardium cross-linked by glutaraldehyde). Ultimate tensile strength (UTS), elastic modulus and suture retention strength were determined using an uniaxial tensile tester in dry and hydrated samples. Suture retention strength was measured by Prolene 4-0 interrupted sutures. Ultrastructure was visualised using Scanning Electron Microscopy.

Results: UTS of $scCO_2$ decellularised porcine and bovine pericardium was comparable to untreated pericardium, while UTS of Peri-Guard® was non-significantly higher (see Table 1). Elastic modulus was relatively high in Peri-Guard® and dry $scCO_2$ decellularised bovine pericardium, but was reduced by half in hydrated condition.

Suture retention strength was higher in dry and hydrated bovine pericardium, compared to Peri-Guard®. Three phenomena were observed: tearing, string cutting and slipping of surgical knot. Preservation of ultrastructure in $scCO_2$ decellularised porcine pericardia (Figure 1) and some deterioration of ultrastructure was observed in Peri-Guard®.

Figure:



Caption: Ultrastructure of both rough and fibrous porcine pericardium decellularised by scCO2, visualised by Scanning Electron Microscopy. Inlay shows anatomic structures of pericardium. Magnification 50x.

Conclusion: Pericardium decellularised by $scCO_2$ has superior mechanical properties with preservation of ultrastructure and higher suture retention strength compared to Peri-Guard®. This makes $scCO_2$ decellularisation a promising technique and further mechanical characterisation, recellularisation capabilities and *in vitro* calcification should be investigated before use in cardiovascular surgery.

ALTERED MUSCLE SYNERGIES DURING GAIT IN CEREBRAL PALSY ARE NOT DUE TO ALTERED KINEMATICS OR KINETICS

Katherine M. Steele[*1], Adam Rozumalski[2,3], Michael Schwartz[2,3]

[1]Mechanical Engineering, University of Washington, Seattle, [2]Biomedical Engineering, University of Minnesota, Minneapolis, [3]James R. Gage Center for Gait & Motion Analysis, Gillette Children's Specialty Healthcare, St. Paul, United States

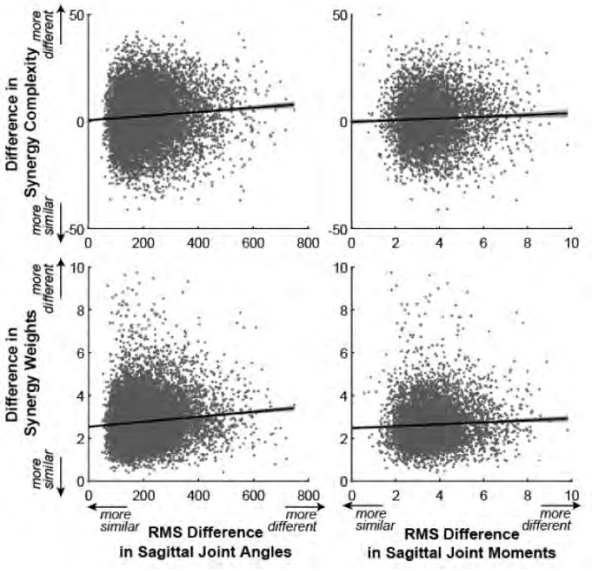
Introduction and Objectives: Walking is a complex movement, requiring the control and coordination of many muscles. For some tasks such as walking, prior research has proposed that part of how we control muscle activity is by activating muscles in weighted groups, commonly called synergies or modes [1]. Synergies are theorized to provide a simplified control strategy compared to controlling each muscle individually. Previous studies have demonstrated that only four to six synergies can describe over 90% of the variance in muscle activity during walking in unimpaired individuals [2]. Further, in individuals with stroke or cerebral palsy (CP), the number of synergies required to describe muscle activity is reduced and theorized to reflect compromised neuromuscular control and impaired function [3,4]. However, whether these changes in synergies reflect altered neural control or other factors, such as altered gait patterns, remains unclear. Biomechanics and task constraints have previously been suggested to impact synergies [5]. If synergies are mechanogenic, then individuals with CP may have altered synergies during gait just because they walk differently than unimpaired individuals.

The objective of this study was to test this theory and evaluate if altered synergies during gait in CP reflect mechanogenic or neurogenic factors. We hypothesized that, if synergies are mechanogenic, then individuals with CP who walk with more similar gait patterns (*i.e.* kinematics and kinetics) should also have more similar synergies. Since individuals with CP have been shown to have altered synergies during gait [4] and use many different gait patterns, this population provides an ideal test case to evaluate this hypothesis.

Methods: We compared the similarity of kinematics, kinetics, and synergies during gait for children with CP who had received motion analysis at a single clinical center prior to February 2013. For 1251 children, we extracted (1) joint angles, (2) joint moments, and (3) electromyography from gait analysis. Electromyography was collected from five muscles per leg and was used to calculate synergies using nonnegative matrix factorization [6]. We then compared 10,000 random pairs of limbs across all subjects to determine if limbs with more similar kinematics or kinetics had more similar synergies. For each pair of limbs, we calculated the root mean square (RMS) difference in sagittal plane joint angles and moments to compare kinematics and kinetics. To compare the similarity of synergies, we calculated two measures. First, to compare synergy structure (*i.e.,* if similar muscles were grouped together), we calculated the L2-norm of the difference in weights of the synergy that explained the most variance in EMG for each limb. Second, we calculated the difference in variance accounted for by one synergy between limbs to compare complexity of synergies (*i.e.,* an individual with more complex synergies would have a lower variance accounted for by one synergy). Linear regression was then used to compare the similarity of the 10,000 pairs of limbs and determine if individuals with more similar kinematics or kinetics also had more similar synergy structure or complexity.

Results: Similarity in joint angles or moments did not lead to greater similarity in synergies (Fig. 1). Differences in synergy weights between individuals were not associated with either differences in kinematics (r^2 = 0.013) or kinetics (r^2 = 0.011). Further, differences in synergy complexity were also not associated with differences in kinematics (r^2 = 0.005) or kinetics (r^2 = 0.001).

Figure:



Conclusion: Altered synergies during gait among individuals with CP are not associated with altered kinematics or kinetics. These results counter our initial hypothesis that individuals with CP have altered synergies because they use different gait patterns compared to unimpaired individuals. Two individuals with CP walking with similar kinematics or kinetics can have very different synergies. Thus, synergies are not purely mechanogenic and difference in gait pattern alone cannot account for altered synergies in CP. Altered synergies in CP may reflect altered neuromuscular control strategies and provide a useful tool to quantify altered control for diagnosis or treatment planning.

LARGER ISOFORMS OF TITIN ARE ASSOCIATED WITH INCREASED SARCOMERE LENGTHS AND SEVERITY OF HIP DISPLACEMENT IN CEREBRAL PALSY.

Kelly A. Larkin-Kaiser [1,*] Venus Joumaa [2] Timothy Leonard [1] Jason Howard [3] Walter Herzog [1]

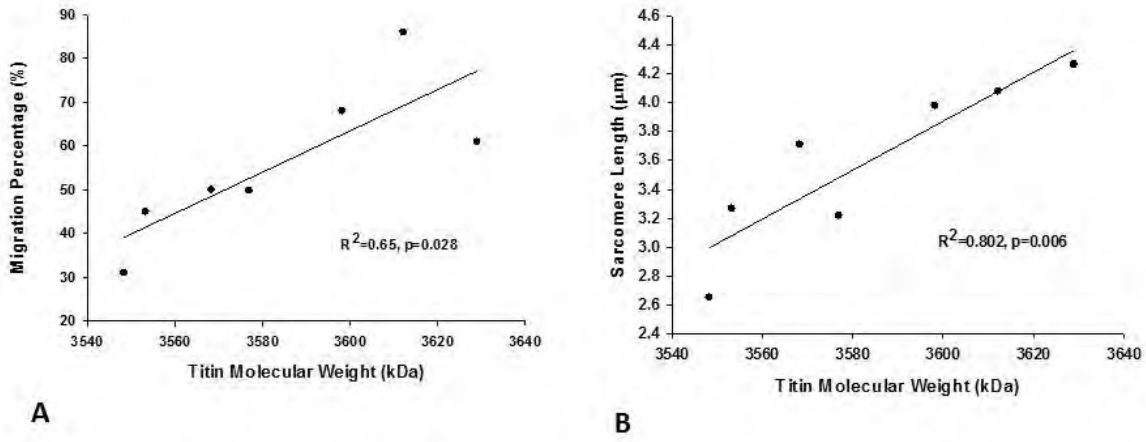
[1]Kinesiology, [2]University of Calgary, Calgary, Canada, [3]Sidra Medical and Research Center, Doha, Qatar

Introduction and Objectives: Cerebral palsy (CP) is an umbrella term describing a spectrum of neurologic compromise secondary to an insult to the developing brain that can lead to musculoskeletal manifestations with growth. The resulting spastic muscle contractures and bony deformities are thought to cause subluxation/dislocation of the hip joint (hip displacement) that often leads to painful osteoarthritis (Soo, Howard, Graham et al, 2006). Previous research has suggested that spastic muscle contractures in CP patients are associated with increased sarcomere lengths for given joint configurations compared to typically developing children (Smith, Lee, Ward, Chambers, & Lieber, 2011). More recent research has suggested that the molecular spring titin may be altered in response to spasticity and contracture (Ottenheijm & Granzier, n.d.). The titin isoform shift may significantly contribute to clinical outcomes by making the overstretched sarcomeres more compliant. However, the muscular changes that occur, and their association with clinical dysfunction, are not clearly understood. Therefore, the purpose of this project was to determine whether changes in skeletal muscle titin isoforms occur in children with CP, and if these changes are associated with increased sarcomere lengths and/or clinical dysfunction.

Methods: Single gracilis muscle biopsies were obtained with consent from children with CP (spastic quadriplegia, GMFCS III-V; n=7) who underwent adductor muscle release surgery for the treatment of hip displacement. Gel electrophoresis was used to estimate the molecular weight of titin isoforms in the gracilis muscle samples. Each biopsy sample generated 10 muscle fascicles used for measurement. Sarcomere lengths were measured at 5 locations along each fascicle using laser diffraction. Radiographic measures were taken pre-operatively and used to calculate migration percentage of the head of the femur from the acetabulum. The severity of hip displacement was determined by measuring by Reimer's migration percentage (MP) from standardized anterio-posterior pelvic x-rays (Valencia, 2010).

Results: The average molecular weight of titin in the gracilis muscle tissue was 3,588 kDa (±26). Sarcomeres from a total of 70 gracilis muscle fascicles were also measured. We observed that the mean sarcomere length in the gracilis was 3.4 μm, compared to less than 3.0 μm in typically developing children. Increased hip displacement was found to be associated with heavier isoforms of titin (R^2=0.65, $p<0.05$), and with increased sarcomere lengths (R^2=0.80, $p<0.05$) (Figure 1).

Figure:



Caption: Figure 1. A) Association between titin molecular weight and migration percentage of the hip B) Association between titin molecular weight and sarcomere length

Conclusion: We observed increased sarcomere lengths in the gracilis muscle biopsies from CP patients with hip displacement. Previous research indicated sarcomere lengths of less than 3.0 µm in the musculature of typically developing children (Smith et al., 2011). Our results also suggest that larger titin isoforms are associated with these long *in situ* sarcomere lengths and with increased severity of hip displacement. It is possible that more compliant isoforms of titin and increased sarcomere lengths are expressed in spastic gracilis muscle tissue as adaptive mechanisms to reduce passive force within the muscle. We show here, for the first time, that larger titin isoforms are associated with morphological changes in children with spastic CP, and that these changes at the structural level are associated with clinical dysfunction.

IMPLEMENTATION AND IMPORTANCE OF THE SUBJECT-SPECIFIC DISTRIBUTION OF FIXED CHARGE DENSITY OF ARTICULAR CARTILAGE IN THE KNEE

Lasse P. Räsänen [1,*] Petri Tanska [1] Mika E. Mononen [1] Pavol Szomolanyi [2] Stefan Zbyn [2] C. C. van Donkelaar [3] Siegfried Trattnig [2] Jukka S. Jurvelin [1] Miika Nieminen [4 5] Rami K. Korhonen [1]

[1]Department of Applied Physics, University of Eastern Finland, Kuopio, Finland, [2]High Field MR Center, Department of Biomedical Imaging and Image-Guided Therapy, Medical University of Vienna, Vienna, Austria, [3]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [4]Department of Diagnostic Radiology, University Hospital, [5]Department of Radiology, University of Oulu, Oulu, Finland

Introduction and Objectives:

Negative charges of glycosaminoglycan (GAG) side chains of proteoglycans (PGs) result in fixed charge density (FCD) of articular cartilage. FCD induces swelling of the tissue and hence plays an important role in load support of the tissue [1,2]. However, it is not known how depth-wise FCD distribution in the knee joint controls cartilage strains. Here, we implement a subject-specific FCD distribution of human knee joint cartilage, as obtained from sodium (^{23}Na) MRI, into a fibril-reinforced poroviscoelastic model with swelling properties (FRPVES). We validate the model by comparing modeled cartilage deformations to experimentally measured deformations *in vivo*, and demonstrate the importance of the subject-specific FCD distribution of knee joint cartilage under static loading.

Methods:

A 3D finite element (FE) model of an asymptomatic knee joint was constructed from manually segmented MR-images (3D-DESS at 7T (MR Centre of Excellence, Vienna, Austria), Fig. 1a,b). ^{23}Na concentration maps of the cartilage tissues were calculated from ^{23}Na MRI after applying corrections for magnetic field inhomogeneity, partial volume effect [3], biexponential T2* and monoexponential T1 to the observed signal [4,5]. The FCD maps and the depth-wise distribution of FCD were further determined for tibial cartilage by relating the obtained ^{23}Na concentrations to ^{23}Na -concentration of synovial fluid (Fig. 1a,f) [6]. For model validation purposes, the subject's knee joint was imaged under axial compression of 120 N (Fig. 1c). The experimentally loaded tibial cartilage was manually segmented and cartilage compression was determined by comparing the segmented cartilage to that obtained under no loading (Fig. 1c).

Cartilage and meniscus were modeled as FRPVES materials including FCD [7–9]. The FCD content of the tibial cartilage, determined from MRI (mean ± SD: 0.17 ± 0.09 mEq/ml), was implemented into the subject-specific model. For comparison, a model with homogeneously distributed FCD (0.17 mEq/ml, mean of the measured FCD) and a model with depth-dependent FCD distribution obtained from literature (0.1-0.2 mEq/ml, Fig. 1e) were created. The FCD distribution in the femoral cartilage (0.1-0.2 mEq/ml) and menisci (0.03 mEq/ml) were obtained from literature [10]. Ligaments were modelled by using linear spring elements [7]. The models were simulated with 120 N axial load for 780 seconds in accordance with the MRI experiment and the depth-wise axial strains in tibial cartilage of the subject-specific model were compared to those of the homogenous and literature models.

Results:

In the medial tibiofemoral contact region of the subject-specific model, the mean axial compression of tibial cartilage was 82 µm after 780 s of creep (Fig. 1d). As measured from the corresponding location of the experimentally compressed joint, the mean cartilage compression was 94 µm. Within the chosen location (Fig. 1a), strains in the model with the subject–specific FCD distribution were increased especially in the superficial tissue (up to +27%), as compared to those in the homogeneous model (Fig. 1f,g). However, strains in the subject–specific FCD model decreased up to -122% in the deep tissue with respect to those in the homogenous model (Fig. 1f,g). In the model with the FCD distribution obtained from literature, strains were in between those observed for two aforementioned models (Fig. 1f,g).

Figure:

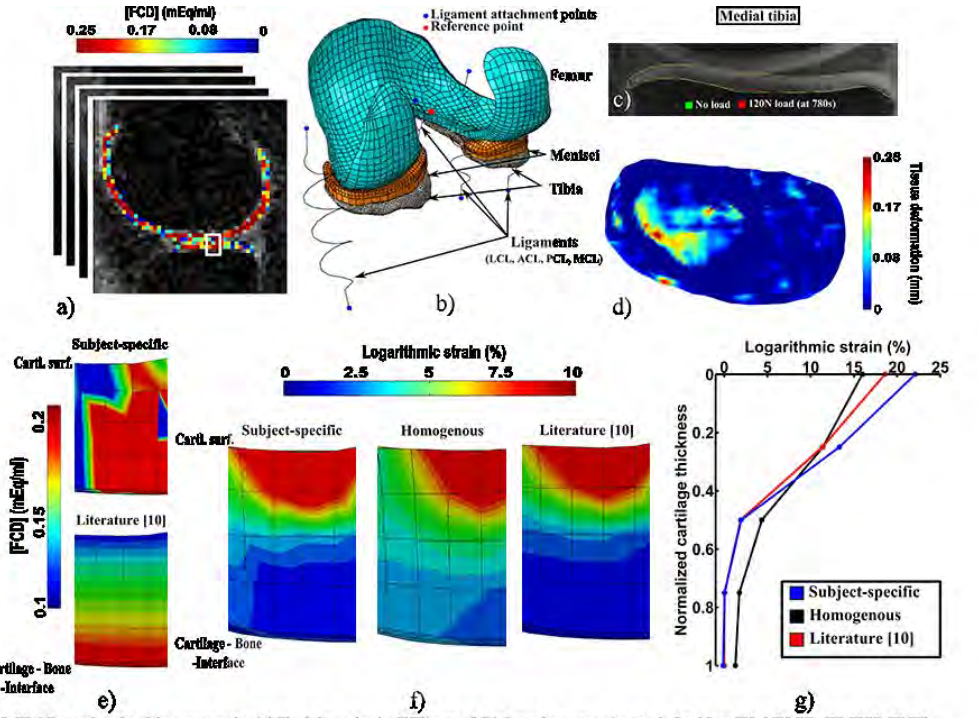

Figure 1: Workflow and results of the current study. **a)** A fixed charge density (FCD)-map of tibiofemoral contact region as calculated from ^{23}Na-MRI (3D-vTE-SPGR: TR/TE$_1$ = 11/1.42 ms, resolution 1.5 x 1.5 x 2.8 mm^3). FCD was determined by relating the calculated ^{23}Na concentrations to that of synovial fluid: $FCD = [^{23}Na_{ref}]^2 / [^{23}Na\ (x,y)] - [^{23}Na\ (x,y)]$, where $[^{23}Na_{ref}]$ = 150mM [6]. **b)** The meshed FE model geometry as segmented from MR images (3D-DESS: TR/TE = 7.81/2.62 ms, isotropic resolution of (0.34 mm)^3). **c)** The segmented and coregistered tibial tissue from imaging done during (red, 3D-DESS: TR/TE$_1$ = 8.68/2.55 ms, isotropic resolution of (0.4 mm)^3) and without static loading (green) (a slice from medial tibial cartilage compartment). **d)** The tibial cartilage deformation of the subject-specific model after 780 seconds of creep. **e)** Subject-specific (above) FCD distribution and that obtained from literature (below, $FCD = 0.11+0.09*h$, where h = normalized tissue depth) the models after the free swelling of the model (location highlighted in a)). **f)** Logarithmic axial strains in the models with patient-specific, homogenous and literature FCD distributions (corresponding location as shown in a) and e)). **g)** Depth-wise distribution of axial strains from f) in each model (0 = tibial cartilage surface, 1 = cartilage-bone interface).

Conclusion:

The presented model with subject-specific FCD obtained from MRI corresponded well with the experimentally measured deformations of the knee joint cartilage *in vivo*. The locally smaller FCD content in the superficial cartilage in the subject-specific model decreased the local tissue stiffness, thereby increasing strains, as compared to the model with a homogeneous FCD distribution. Correspondingly, increase in tissue stiffness in the deep tissue (due to higher amount of FCDs) decreased strains, as compared with those in the homogenous model. For the chosen location, local tissue strains

in the subject-specific model were close to those obtained from the model with the FCD distribution captured from literature.

By taking into account FCD of cartilage, more realistic estimation of tissue strains and stresses in the knee joint to mechanical loading can be obtained. The model may provide a feasible method for evaluating the effect of PG loss on tissue mechanics, as well as the onset and progression of OA in the human knee joint.

REAL-TIME VIRTUAL MUSCLE CONTROL FOR POWERED PROSTHESES AND EXOSKELETONS

Sandra K. Hnat [1,*] Antonie van den Bogert [1]

[1]Mechanical Engineering, Cleveland State University, Cleveland, OH, United States

Introduction and Objectives: Powered prosthetic limbs are theoretically capable of replicating able-bodied movements. These devices are typically actuated by single-joint electric motors with time-varying linear impedance control. Though substantially better than passive prostheses, able-bodied gait is usually not achieved. We hypothesize that a more muscle-like actuation system can improve performance and simplify the feedback control. Muscles are actuators with nonlinear viscoelastic properties and internal dynamics, often crossing multiple joints. It has been shown through simulation that these properties contribute substantially to the stability of walking [1]. Here we consider the possibility of actuating a powered prosthetic system with torques generated by a real-time simulation of muscle dynamics.

Real-time simulation is challenging because the ordinary differential equations (ODE) that represent muscle dynamics are highly nonlinear and have near-singularities. Consequently, fixed step ODE solvers can become unstable and variable-step solvers will be slow due to small time steps. An alternative implicit formulation and solution method has the potential to achieve accurate results with minimal computation time [2].

The purpose of this paper is to develop and test a real-time simulation of a human muscle actuation system that generates knee and ankle torques for an above knee prosthetic device. The virtual muscle system consists of six muscles, and is driven by real-time joint angle data and muscle excitation signals.

Methods: For proof of concept, we used a planar leg model with six muscles, three of which were monoarticular groups (Vasti, Soleus, Tibialis Anterior) and three were biarticular (Rectus Femoris, Hamstrings, Gastrocnemius). The inputs to the system are the joint angles (q) at the hip, knee, and ankle and the control signals (u) for the six muscles. Musculotendon length of each muscle, a required input for simulation of muscle dynamics, is computed from the three joint angles.

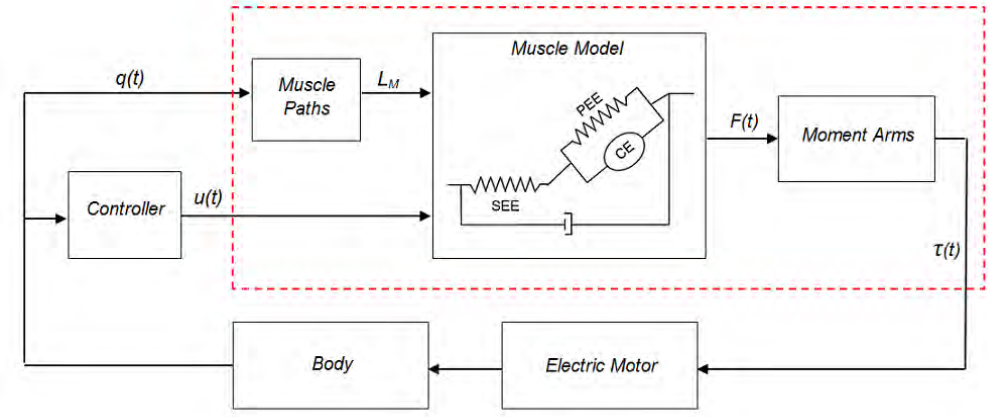
Muscles were represented by a Hill-type model with a contractile element (CE), series/parallel elastic elements (SEE/PEE), and a small amount of viscous damping in parallel to the contractile element. The CE has standard force-velocity and force-length properties, while PEE and SEE are modeled as nonlinear elastic. Muscle contraction dynamics was formulated as a first-order implicit differential equation (IDE). An additional first-order IDE represented the activation dynamics. The force generated by each muscle was multiplied by moment arms to obtain its contribution to the knee and ankle torques. Figure 1 is a block diagram describing the inputs and outputs of the model, in which the red box indicates the scope of this study.

Tests were performed using joint angle time histories q(t) for 30 seconds of normal walking and 1 Hz sinusoidal test signals for the muscle excitations u(t). In a prosthetic device, the former would be real-time encoder data, while the latter would be generated by a control system. Simulations were performed in Matlab with a first order Rosenbrock solver [2] using fixed time steps ranging from 0.08 to 16.0 ms. Joint torques generated by the model were compared to the result

from the smallest time step in order to determine numerical error in the simulations as a percentage of the maximum moments. Computation times were measured in all tests.

Results: Muscle forces and joint torques responded appropriately to sinusoidal muscle activations. Table 1 shows how the accuracy and speed of the simulation depended on the integrator step size. RMSE was proportional to step size, due to the first order approximation used. At 0.31 ms, the simulation was just faster than real-time and the simulation errors were well below 1%. Substantially larger time steps still resulted in acceptable accuracy. For time steps larger than 10 ms, the simulation was unstable.

Figure:



Conclusion: The tests demonstrated joint torques can be generated by a real-time simulation of muscle dynamics. Computation time was well within the requirements for real-time, even in the high-level Matlab language. The muscle dynamics and differential equation solver only require simple mathematical operations and no software libraries, making them suitable for implementation on an embedded system. We conclude that this virtual muscle actuation system can be used to drive the electric motors in a prosthesis in order to better replicate the control and dynamics of able-bodied gait.

Table:

Simulation step size (ms)	RMS error in knee moment (%)	RMS error in ankle moment (%)	Solution time (s)
0.1	0.02	0.01	57.8
0.18	0.08	0.04	32.8
0.31	0.20	0.10	18.7
0.54	0.40	0.20	10.8
0.95	0.76	0.38	6.0
1.68	1.39	0.69	3.9

CORTICAL MODULATION OF ABERRANT LOWER LIMB MUSCLE SYNERGIES FOLLOWING STROKE

Andrew Q. Tan [1,*] Yasin Dhaher [2]

[1]Neuroscience, [2]Biomedical Engineering, Northwestern University, Chicago, United States

Introduction and Objectives: Growing evidence demonstrates unique synergetic signatures in the lower limb(LL) post-stroke, with a specific across-plane and across-joint representations. Observations of such neural constraints include coupled cross planar kinetic outflow[1] and altered muscle synergy structure[2]. Recent findings from our lab illustrated that additional activation of the lesioned hemisphere (L-H) upregulates the expression of these aberrant muscle synergies in the LL [3]. While the inhibitory role of the ipsilateral hemisphere in the upper limb has been widely reported, examination of the role of the contralesional hemisphere (CON-H) in modulating these synergies in the LL following stroke is lacking. Accordingly, we test the hypothesis that stimulation of L-H and CON-H motor cortices will have differential effects on the motor evoked potential (MEP) patterns of the paretic LL. We proposed a novel TMS paradigm to identify patterns of MEPs across multiple LL muscles during a task where synergistic actions have been reported.

Methods: 10 control and 12 chronic stroke participants with single hemispheric stroke were recruited. Motor evoked potentials (MEP) were elicited in 8 LL muscles using single pulse TMS. Surface electromyography (EMG) were recorded from: vastus medialis (VM), vastus lateralis (VL), rectus femoris, adductor longus (ADD), tibialis anterior (TA), medial gastrocnemius, and biceps femoris. Single pulse TMS was delivered using a Magstim 200 stimulator via a 110 mm diameter double-cone coil. The coil position was incrementally adjusted to locate the ADD hotspot over L-H motor cortex contralateral to the test limb (stroke paretic limb). Optimal coil position and intensity was mapped as the lowest stimulation intensity required to evoke ADD MEPs of 50 μV in peak-to-peak amplitude in 3 of 5 consecutive trials. The hotspot for the test limb ADD was similarly mapped for stroke contralesional hemisphere (CON-H) or control ipsilateral hemisphere to test limb. Stimulator output for the CON-H was increased in order to match contralateral (cMEP) and ipsilateral (iMEP) ADD amplitudes.

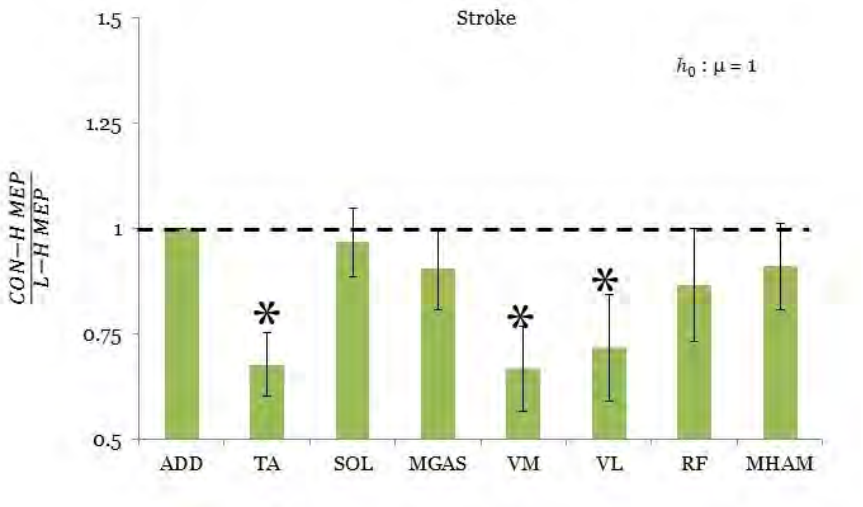
Participants were isometrically locked in the toeoff gait posture in an instrumented exoskeleton with 3 6-DOF load cells used to measure the interaction forces and moments. Participants matched isometric hip adduction torques at 40% of their maximum while receiving instantaneous visual feedback in the form of moving a circular cursor. A successful trial was considered if the participant matched the target torque within ±5% of the torque magnitude and direction and hold for a minimum of 200ms.

For each trial the TMS coil was placed over the hotspot location for either hemisphere. When the participants successfully matched the target adduction torque, the TMS device was triggered by software. Matched ADD MEPs together with nontargeted muscles were simultaneously recorded. 10-30 trials were performed for each hemisphere. An 80 ms window following the TMS pulse was searched for the MEP onset when 5 consecutive points in the EMG trace were above 3 standard deviations of the mean pre-TMS EMG activity. MEP amplitudes were measured peak-to-peak and calculated as

the difference between the background activation and the average of a 20 ms window centered at the peak MEP rectified pulse. The ratio of the mean iMEP amplitude over the mean cMEP amplitude was quantified for each muscle. A statistical value less than one indicate a reduction in iMEP amplitude relative to the cMEP amplitude following TMS of the ipsilateral hemisphere.

Results: By quantifying the CON-H / L-H MEP ratio across muscles, we characterized a significant inhibition of aberrant MEP coupling between ADD and VM (p=0.0078) and VL (p=0.047) following CON-H stimulation exclusive to the stroke group (ANOVA,p=0.028), an inhibition that was muscle dependent (ANOVA, p= 0.039). We find a significant reduction of TA MEPs in both groups following ipsilateral hemisphere stimulation (p=0.0014 stroke; p=0.015).

Figure:



Conclusion: Our results indicate that stimulation of CON-H reduced the expression of abnormal synergistic activations in individuals with stroke. Our observations seem incongruent with the notion of maladaptive motor output from CON-H post stroke suggested in the UL. Furthermore, a majority of the interhemispheric MEP onset latency differences occur below 3ms, consistent with the interpretation of ipsilateral corticospinal projections to the LL despite equivocal findings of their functionality the UL. Combined with the systemic inhibition of TA across groups, we argue that the ipsilaterally mediated MEP signature provides indirect evidence of inhibitory intracortical connectivity between abnormally synergistic muscles. This study takes an important step in exploring the relation between CON-H cortical reorganization and the modulation of abnormal LL muscle synergies post stroke.

EMERGING SCIENTIST AWARD

MUSCLE SYNERGIES AS A STRATEGY FOR COORDINATING REDUNDANT MOTOR SYSTEM

Shota Hagio
Research Fellow of the Japan Society for the Promotion of Science, Japan
Graduate School of Human and Environmental Studies, Kyoto University, Japan

To simplify a redundant degree of freedom, the concept of muscle synergies was proposed, which modularly organize a lot of muscles as the same group (Tresch et al., 1999). Although muscle synergies were calculated in a variety of movements, the neural origin remains unclear. In this lecture, I will introduce a series of our studies to clarify the underlying mechanisms of muscle synergies as neural system.

The first important question is whether the central nervous system (CNS) generates appropriate motor output through a neural circuit of muscle synergies. We demonstrated that the total activation of approximately 7 extracted muscle synergies from 15 muscles spanning knee and hip joints correlated to the target-directed variance of isometric endpoint force around a right ankle (Hagio and Kouzaki, 2015, Exp Brain Res). This result implied that the CNS indeed produces appropriate endpoint force using the neural system of muscle synergies.

Although dynamical movements involve the change of the force-generating capability of muscles due to the change of the physiological parameters, how did the CNS modulate the recruitment of muscle synergies? To clarify the question, we extracted lower-limb muscle synergies during isometric force generation with various combinations of knee and hip joint angles. Therefore, the CNS flexibly regulated the descending input to muscle synergies with merging or decomposing depending on the force generating capability of muscles (Hagio and Kouzaki, 2015, J Neurophysiol).

The flexibility of muscle synergies describing above permits a modular control of dynamical movements such as walking and running. We examined muscle synergies during a gait transition between walking and running, in which complicated control would be particularly needed to change different kinematic characteristics. As a result, regulating the activation timing of the specific muscle synergies, which dominated plantar flexor muscles, enabled a gait transition (Hagio et al., 2015, Front Hum Neurosci).

The low-dimensionality of muscle synergies is advantageous to generate movements whereas it is unclear what is a functional role of muscle synergies during motor learning. We constructed a descending neural network model including 3 intermediate layers, which were regarded as 1000 neurons in primary motor cortex, 4 spinal interneurons (muscle synergies) and 18 muscles. This model then learned the isometric force generation around a wrist. Consequently, the existence of muscle synergies demonstrated faster adaptation to a rotational perturbation than the absence of muscle synergies.

In conclusion, the flexibility and robustness of muscle synergies make a significant contribution to appropriate movement learning and production despite redundancy in motor system. Because “muscle synergy” is a fundamental topic to understand all motor control studies, a further study will be important to identify the existence of muscle synergies.

TESTING MODEL-BASED CONCLUSIONS ON THE OPTIMAL CONTROL OF HUMAN MOVEMENT USING FORMAL STATISTICAL ANALYSES

Ross H. Miller [1,*] Farzad Ehtemam [1]

[1]Department of Kinesiology, University of Maryland, College Park, United States

Introduction and Objectives: Optimal control theory (OCT) has made many elegant and reasonably accurate predictions of human motor behavior. However, the traditional implementation of OCT in biomechanics [1] is extremely computationally demanding for large-scale musculoskeletal models. Consequently, most model-based OCT studies on locomotion have used a single generic model. With data from only one "subject" that does not reflect the biological variance present in even the healthy human population, the generalizability of such results is unclear.

Recent simulation methods can rapidly generate many OCT simulations in practical amounts of time [2], opening the possibility of performing "virtual" experiments with multi-subject datasets that can undergo formal statistical analysis as is standard for laboratory-based experiments, adding an important new element of validity to simulation of human movement.

Our objective was to test the hypothesis that conclusions on locomotor control from OCT are robust to healthy variation in anthropometric and muscular properties.

Methods: We used implicit direct collocation [2] to generate predictive simulations of human walking with models representing 10 subjects drawn from standard normal parameter distributions (Table 1). The basic structure of the model was the same for all 10 subjects: 12 degrees of freedom, 24 Hill-based muscles, and a model of muscle energy expenditure [3].

For each subject, walking was simulated on a temporal grid of 101 nodes/step. We first performed a data-tracking simulation that optimized the musculoskeletal states, muscle excitations, and step duration to track mean human experimental data [4] with minimum metabolic cost. The data-tracking result was used as the initial guess for predictive simulations with two different cost functions:

"Minimum Fatigue": minimize the largest muscle activation.

"Minimum Effort": minimize sum of muscle activations, each weighted by muscle mass.

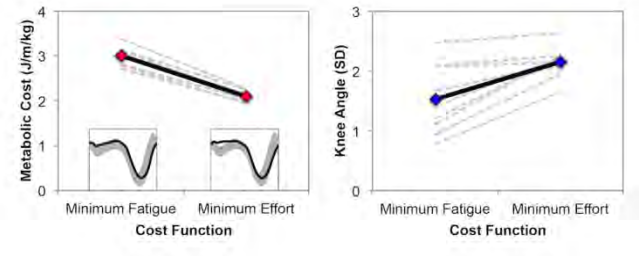
Equality constraints enforced dynamic consistency, periodicity and bilateral symmetry, and Froude number 0.14. The average deviation of the knee angle from mean human experimental data in the first half of stance [4] was expressed in multiples of the experimental standard deviation (SD). Metabolic cost and average knee angle deviation was compared between cost functions using matched-pair Student's t-tests (critical $p = 0.05$).

Results: A single simulation required ~ 20 minutes in MATLAB on an iMac. The models tracked the mean human gait data to an average deviation of 0.60±0.03 SD with a metabolic cost of 3.41±0.16 J/m/kg.

The gross metabolic cost was lower for the Minimum Effort simulation (2.10±0.11 J/m/kg vs. 3.00±0.19 J/m/kg, $p < 0.00001$). The range in differences was 0.77-1.12 J/m/kg (Fig. 1).

The average knee angle deviation was greater for the Minimum Effort simulation (2.16±0.25 SD vs. 1.53±0.55 SD, $p = 0.00084$). The range in differences was 0.07-1.14 SD. Minimum Effort tended to predict a straight knee in stance, while Minimum Fatigue predicted stance phase knee flexion (Fig. 1).

Figure:



Caption: Metabolic cost (left) and knee angle accuracy (right) when using the "Minimum Fatigue" and "Minimum Effort" cost functions. Dashed lines are simulations with the different models, solid lines are means over all 10 models. The inset figures in the left panel show the average knee angle waveforms predicted by each cost function, compared to the experimental data.

Conclusion:

The qualitative consistency of predicted gaits between subjects suggests it may have been safe to draw conclusions from one subject. However, the difference in the average knee angle deviation was over 1.0 SD for three subjects and under 0.2 SD for three others. These data may suggest different conclusions if considered in isolation. Simulations with multiple model parameter sets were needed to discover the average behavior and the consistency between subjects. Simulation studies have often made modeling decisions for computational speed rather than physiological fidelity, or excluded particular analyses due to computational time rather than relevance. With rapid advances in computing power and simulation methods, the validity of these limitations is diminishing. We suggest that simulation studies whenever possible should be held to the same standards of statistical rigor applied to laboratory-based studies.

Table:

Model	Height (m)	Mass (kg)	Muscle (kg)	Speed (m/s)
1	1.66	61.0	20.9	1.10
